

# **GENETIC ALTERATIONS IN PROSTATE CANCER: EVALUATING THEIR BIOMARKER POTENTIAL AND ROLES IN THERAPEUTIC RESPONSE AND RESISTANCE**

By  
Samantha Danielle Torquato

A dissertation submitted to Johns Hopkins University in conformity with the  
requirements for the degree of Doctor of Philosophy

Baltimore, Maryland  
August 2018

# ABSTRACT

Prostate cancer (PCa) continues to be a leading cause of cancer-related death in United States men due to the subset of patients who develop metastatic disease. In spite of recent advances, two substantial clinical challenges remain today: identifying who is at risk for (1) metastatic recurrence and (2) developing resistance to current therapies. In order to address these two main challenges, three novel approaches were taken to evaluate the potential of PCa genetic alterations as biomarkers and the roles that these genetic alterations have in therapeutic response and resistance. For our first study, genetic aberrations discovered by the next-generation sequencing (NGS) of patients' primary tumor DNA (which was isolated from radical prostatectomy samples) were probed for by droplet digital PCR (ddPCR) in the corresponding patient's plasma-derived cell-free DNA (cfDNA) isolated before radical prostatectomy. Determining if it is possible to assess the genetic landscape of primary PCa by liquid biopsy, may ultimately lead to the discovery of biomarkers for disease risk stratification as well as the ability to better predict disease outcomes and treat localized PCa patients. For our second study, metastatic castration-resistant prostate cancer (mCRPC) patients were prospectively enrolled in order to validate gene alterations, such as androgen receptor (*AR*) ligand-binding domain (LBD) mutations and/or *AR* copy number (CN) gain, detected in cfDNA as markers of enzalutamide and abiraterone resistance. Here, we show that *AR* LBD missense mutations are associated with a shorter progression-free survival (PFS). In addition, loss of the tumor protein p53 (*TP53*) gene and defects in the phosphoinositide 3-kinase

(PI3K) pathway are associated with a worse overall survival (OS). In our third study, the CRISPR/Cas9 system was used to generate an isogenic panel of PCa cell lines, containing both individual and multiple hotspot AR LBD mutations. The findings from these *in vitro* models will illuminate the biological role that these genetic alterations have in resistance to contemporary next-generation therapies, such as abiraterone and enzalutamide. Taken together, our studies provide valuable insight on how to better identify which PCa patients are at risk for developing lethal disease and resistance to current treatments.

**Thesis Readers:** Paula J. Hurley, Ph.D.

Srinivasan Yegnasubramanian, M.D., Ph.D.

# ACKNOWLEDGEMENTS

There are several people I wish to acknowledge for the support they have given me throughout my graduate school career. Without the following colleagues, friends and family, this dissertation would not have been possible.

First, I would like to thank my thesis advisor, Dr. Paula J. Hurley. Over the past four years, you have taught me what it takes to be an effective principle investigator, to run a productive laboratory, and to succeed in science. Thank you for having an open-door policy, which allowed for a constant exchange of scientific ideas. I would also like to thank Dr. Ben H. Park for inviting me to your laboratory in order to learn cutting-edge science firsthand and for welcoming me into your home for all of the major holidays. I would like to acknowledge the members of my thesis committee: Dr. Srinivasan Yegnasubramanian, Dr. John T. Isaacs, and Dr. Shawn E. Lupold. Every aspect of my thesis project would not have been as successful without your mentorship and wisdom.

The members of the Hurley Laboratory have contributed to my graduate school experience by sharing their technical talents and scientific knowledge as well as providing moral support and loyal friendships. Robert Hughes (Rob), you have been more than a colleague, classmate, and friend; I finally know what it's like to have a big brother. Rebecca Miller (Becky), thank you for the countless hours you spent ordering supplies so that I could complete my thesis project and for being a good listener.

The members of the Park Laboratory have been a supportive influence throughout graduate school, always willing to share their expertise and teach me

new techniques. Dr. W. Brian Dalton, the scientific discussions we had over the years greatly enriched my Ph.D. experience, and Chapter 3 of this dissertation would not have been possible without your guidance. Dr. Natasha Hunter, the patient room was truly not as fun until we started working together, and Chapter 1 of this dissertation would not have been possible without you.

I would also like to thank the administrators of Cellular and Molecular Medicine (CMM) for making my dreams come true when I was accepted into this Ph.D. program. Dr. Rajini Rao and Dr. Robert A. Casero, Jr., thank you for your advice and inspiration throughout my graduate school experience. To Colleen Graham and Leslie Lichter, you are two of the strongest and fiercest women I know; thank you for all of the laughs, hugs, and unconditional support. To my CMM classmates: from our first Thanksgiving to our trip to see the cherry blossoms in DC, from our coating ceremony to the many weddings, I want to say thank you for making graduate school memorable. To Jessica Miciak (Jess), thank you for the sisterly love you have shown me; this journey would not have been the same without you and your humor. To Ruchama Steinberg (Roo), when you meet someone from home, it doesn't seem like home is that far away. Thank you for being a true friend and trustworthy confidant.

Lastly, this dissertation is dedicated to my family. Mom and Dad, thank you for your unconditional love and for all of the sacrifices you have made so that I could achieve my dreams and accomplish all of my personal and professional goals. To my sister, Melissa, I am grateful for your unwavering belief in me and for all of the times you have motivated me to continue moving forward. To my

grandparents, thank you for your endless love and encouragement as well as the constant reminder that you are proud of me. I would not be where I am today without all of you.

## **Genetic Alterations as Potential Biomarkers for Localized Prostate Cancer**

## **Introduction**

### *Prostate Cancer (PCa) and PCa Screening*

PCa is the second most common cancer in men worldwide [1]. It is estimated that in 2018, PCa will be diagnosed in 164,690 men in the United States alone and that 29,430 men will die of this disease, which is equivalent to 9% of the total cancer-related deaths in United States men [2]. This high incidence of PCa can be attributed to multiple genetic and demographic factors, such as age, family history, and race [3]. However, due to advances in PCa screening, the five-year relative survival rate for PCa, regardless of race and disease stage at diagnosis, is 99% [2].

The Prostate-Specific Antigen (PSA) blood test has allowed for the early detection of PCa. In fact, regular PSA screening aids in the diagnoses of men with prostatic carcinoma, on average, 10-12 years earlier in their natural history of the disease than those men who remain unscreened [4-7]. Thus, due to the PSA blood test, the majority of initially detected PCa (~90%) is still localized disease [4]. Today, it is widely acknowledged that the PSA blood test can detect high levels of circulating PSA that may be present due to noncancerous conditions of the prostate, such as inflammation. Therefore, the PSA blood test alone cannot be used as a reliable diagnostic tool for primary PCa, but can still assist in the monitoring of disease progression once the disease has been confirmed [8].

### *Localized PCa and Disease Risk Stratification*

Localized PCa is a clinically and molecularly heterogeneous disease, which is best highlighted by the fact that some patients are cured of their indolent disease with initial therapy, while others will die from their more aggressive cancers [9]. It is due to this subset of aggressive and metastatic cancers that PCa remains a leading cause of death. Over the past two decades, many researchers have attempted to gain a better understanding of who is at risk for metastatic disease in order to positively impact clinical disease management. Earlier research efforts focused on developing accurate disease risk stratification systems, relying on both clinical and pathological parameters. These initial systems, which involved Gleason grading or assessing free PSA levels alone, have been shown to be severely deficient in predicting disease outcomes [10-12]. Today, enhanced risk stratification systems, such as five-grade grouping and the Prostate Health Index (PHI), exist [13, 14]; however, due to the heterogeneous nature of PCa, these systems do not have perfect predictive abilities. Thus, molecular and genetic features of localized PCa are still being studied with the intention of further improving the ability to distinguish between indolent and aggressive disease in the clinic.

### *Genetic Landscape of Primary PCa*

Multiple studies have identified genetic alterations (such as mutations, copy number variations, rearrangements and fusions) in primary PCa, aiming to determine if the genomic status of a tumor could be used to additionally

differentiate between low- and high-risk disease [15-22]. In 2015, a comprehensive molecular profiling study of primary PCa found that 74% of tumors could be assigned to one of seven genomically distinct subtypes (Figure 1.1) [9]. The mutually exclusive subtypes defined by this study were fusions in 1) ETS-related gene (*ERG*), 2) ETS variant 1 (*ETV1*), 3) ETS variant 4 (*ETV4*), 4) Friend leukemia virus integration 1 (*FLI1*) and mutations in 5) Speckle-type BTB/POZ protein (*SPOP*), 6) Forkhead box A1 (*FOXA1*), 7) Isocitrate dehydrogenase 1 (NADP+) (*IDH1*) [9].

Fusions between *ERG* or the other members of the ETS family of transcription factors and the promoters of androgen receptor (AR)-targeted genes are extremely common in localized PCa. In fact, the *TMPRSS2:ERG* gene fusion is the most common genetic alteration in primary PCa, occurring in 40-50% of tumors [9, 23, 24]. However, multiple studies in the past decade have shown that *TMPRSS2:ERG* gene fusions do not significantly correlate with long-term patient outcomes, the risk of biochemical recurrence, or even PCa-specific mortality [25, 26].

While somatic point mutations are less common in PCa than in other solid malignancies, genetic mutations have been discovered in recent years. *SPOP* missense mutations occur in up to 15% of clinically localized PCa, making *SPOP* one of the most commonly mutated genes in primary PCa [9, 16, 17, 27]. The *SPOP* gene encodes for a substrate-binding adapter protein that provides specificity to a CUL3-based E3 ubiquitin ligase [28]. To date, multiple oncogenic substrates of *SPOP* have been discovered, such as *DEK* [29], tripartite motif-

containing 24 (TRIM24) [29, 30], and AR [31, 32]. The Y87, F102, W131, and F133 residues are located in the SPOP protein's MATH domain, are important for substrate-binding, and are the most commonly mutated residues in primary PCa [16, 28]. In 2017, Blattner et al. showed with a conditional mouse model that mutated SPOP drives prostate tumorigenesis *in vivo* by activating both AR and phosphatidylinositol-4,5-bisphosphate 3-kinase (PI3K)/mechanistic target of rapamycin (mTOR) signaling [33].

The *FOXA1* gene encodes for a transcription factor that has been previously shown to target the *AR* [34], to be required for prostate epithelial cell differentiation [35], to play a role in PCa oncogenesis [36], and to promote cell cycle progression in castration-resistant prostate cancer (CRPC) [37]. In multiple studies, it has been found that *FOXA1* mutations occur in about 4% of localized PCa [9, 16, 38]. Mutations in *FOXA1* have been found in its DNA-binding domain, Forkhead domain, and C-terminal trans-activating domain [9, 16, 38]. Today, it is still unclear if these mutations impact FOXA1's binding to its DNA targets or interaction with its transcriptional coregulators [9, 16]. Meanwhile, the *IDH1* gene encodes for the cytoplasmic form of IDH [39]. *IDH1* mutations have been shown to occur in only 1 to 3% of primary PCa and significantly correlate with early onset disease [9, 39, 40].

The following genes have also been discovered to be consistently altered in primary PCa across multiple studies; however, they do not necessarily form mutually exclusive subgroups. The oncogene PI3K-alpha (*PIK3CA*) and the tumor suppressor phosphatase and tensin homolog (*PTEN*), both of which are

genes in the PI3K/mTOR pathway, have been found to be altered in 4% and 17% of localized PCa, respectively [9, 16]. Interestingly, *PTEN* gene deletion is an established prognostic biomarker in PCa, as it is reproducibly associated with poor outcomes [41-43]. Other tumor suppressor genes harboring aberrations in primary PCa are lysine methyltransferase 2D (*KMT2D*; 3%) and tumor protein p53 (*TP53*; 7%) [9, 16]. In the past decade, *TP53* mutations have been shown to significantly contribute to tumor recurrence in PCa [44]. Lastly, lysine demethylase 6A (*KDM6A*; < 2%), mediator complex subunit 12 (*MED12*; 5%), and sodium voltage-gated channel alpha subunit 11 (*SCN11A*; 5%) genetic aberrations have also been identified in localized disease. A recent study concluded that genetic alterations in epigenetic regulators and chromatin remodelers, such as *KMT2D* and *KDM6A*, are significantly enriched in metastatic tumors when compared to primary tumors, implying that these genetic alterations could be potential biomarkers for high-risk disease [45]. While aberrations in a few of the aforementioned genes are known to contribute to poor outcomes in PCa patients, the significance of the other previously discussed genetic alterations as they relate to PCa progression is still unclear [9, 16].

### *Tissue vs. Liquid Biopsies*

Today, tissue biopsies are collected from patients for diagnostic purposes; however, the molecular and genetic landscape of primary and metastatic tumor biopsies can also be evaluated. In fact, Gerlinger et al. (2012) characterized multiple tumor specimens obtained from the same patient and determined that

there were spatial (genomic differences between separate regions of the same tumor) and temporal (genomic differences between the primary tumor and recurrences) heterogeneities amongst this patient's samples [46]. Thus, tissue samples provide a limited view of a tumor's genomic makeup at only one point in time. In addition, tissue biopsies are extremely invasive and can have high complication rates [47].

In recent years, liquid biopsies have been considered as the replacement for tissue biopsies as they better capture genomic heterogeneity of a given patient's disease and allow for consistent monitoring throughout the natural history of one's disease [47, 48]. Additionally, liquid biopsies are minimally invasive and easily obtainable [47]. One type of liquid biopsy is the collection of a patient's blood so that circulating cell-free DNA (cfDNA) can be isolated and examined for diagnostic genetic aberrations. Since it has been previously shown that the amount of circulating cfDNA correlates with disease burden [49] and that a portion of cfDNA is tumor-derived [50], it is thought that liquid biopsies will have the ability to benefit all stages of cancer therapy (i.e. from assisting in the early diagnosis of primary disease to predicting treatment response in patients with metastatic disease).

### *Liquid Biopsies for Primary PCa*

In the past decade, many studies have discovered how plasma-derived cfDNA from metastatic PCa patients can be utilized to predict disease recurrence and treatment response [51-59]. However, there has been very little research

concerning the use of cfDNA in order to diagnose early PCa, determine biomarkers that risk-stratify localized disease, or even improve prognostic abilities before patients receive surgery and/or radiation. In fact, since the majority of primary PCa is still contained within the prostate itself when initially diagnosed and circulating cfDNA correlates with disease burden, it is unknown if cfDNA is even reliably detectable in localized PCa patients or those with a low disease burden.

The primary goal of this study was to determine if genetic aberrations discovered by the next-generation sequencing (NGS) of patients' primary tumor DNA (which was isolated from radical prostatectomy samples) could also be found by droplet digital PCR (ddPCR) in the corresponding patient's plasma-derived cfDNA isolated before radical prostatectomy. The secondary aim of this study was to determine if the same genetic aberrations discovered in the primary tumor DNA and pre-radical prostatectomy, plasma-derived cfDNA samples could additionally be probed for by ddPCR in the corresponding patient's plasma-derived cfDNA isolated after radical prostatectomy. The findings from this study will determine if it is possible to assess the genetic landscape of primary PCa by liquid biopsy. Ultimately, this study could lead to the usage of a noninvasive technique in order to discover potential biomarkers for disease risk stratification as well as better predict disease outcomes and treat patients with localized PCa.

## **Materials and Methods**

### *Patients and Sample Collection*

This biomarker study was approved by the Johns Hopkins Medicine Institutional Review Board (IRB). All patients provided written informed consent prior to enrollment. Eligibility criteria included patients diagnosed with localized PCa who had no documented metastatic disease by either computed tomography (CT) or by bone scans with technetium-99m-labeled methylene diphosphonate. Patients were enrolled between May 2013 and March 2014 at the Johns Hopkins Hospital (Baltimore, MD). The 17 patients enrolled in this study had histologically confirmed prostate adenocarcinoma and radical prostatectomies. Radical prostatectomy samples were formalin-fixed and paraffin-embedded (FFPE). In a dedicated bleach- and ultraviolet (UV)-cleaned hood, primary tumor DNA was isolated from the FFPE samples using QIAamp® DNA FFPE Tissue Kit (Qiagen; Cat. #56404) as per the manufacturer's protocol. To limit cross-contamination of samples, no more than four patient samples were processed at a time.

Blood was collected before and after radical prostatectomy for all 17 subjects. Clinical follow-up data, including patient PSA levels, were also obtained before and after radical prostatectomy for all 17 subjects.

### *Plasma and cfDNA Isolations from Blood Samples*

Three, 10mL blood samples were collected in Streck BCT tubes pre- and post-surgery for each patient. Blood was stored at room temperature and then processed for plasma isolation within 24 hours. To optimize patient sample integrity and to limit DNA contamination, plasma was extracted in a bleach- and UV-cleaned hood specifically for plasma extraction in a room dedicated for blood processing, storage, and cfDNA isolation. Plasma was extracted from blood by centrifugation for 10 minutes at 1500 x g followed by a second centrifugation for 10 minutes at 3000 x g as previously described [60-63]. Plasma was stored at -80°C in 1.5mL aliquots. In a dedicated bleach- and UV-cleaned hood, cfDNA was extracted from plasma using the QIAamp® Circulating Nucleic Acid Kit (Qiagen; Cat. #55114) as per the manufacturer's protocol. To limit cross-contamination, samples were processed individually.

### *Deep NGS*

GeneRead™ DNaseq Custom Mix and Match Targeted Panel V2 (Qiagen; 47 genes; 352,096 bases; Table 1.1) was used to prepare libraries of the primary tumor DNA isolated from the FFPE samples for NGS as per the manufacturer's protocol. NGS libraries were prepared in a dedicated bleach- and UV-cleaned hood. Primary tumor DNA was quantified using Qiagen's QIAseq™ DNA QuantiMIZE Assay (DNQC-100Y-F) as per the manufacturer's protocol. Between 0.8 and 13.0ng of primary tumor DNA was used for library generation. Samples were PCR-amplified using Qiagen's GeneRead™ DNaseq Panel PCR

Reagent V2 (Cat. #181942) for 22 cycles as per the manufacturer's protocol. PCR panel amplicons were purified using AMPure XP beads (Beckman Coulter, Cat. #A63880) and then quantified by the Agilent 2100 Bioanalyzer. Qiagen's GeneRead™ DNA Library Prep I Kit (Cat. #180435) and GeneRead™ Adapter I Set A and B 12-plex (Cat. #180985 and #180986, respectively) were used to construct all libraries according to the manufacturer's instructions. Purified libraries were amplified using Qiagen HiFi PCR Master Mix for 5 cycles according to the manufacturer's protocol. Purified libraries were amplified using Qiagen HiFi PCR Master Mix for 5 cycles according to the manufacturer's instructions. Prepared libraries were quantified using QIAseq™ Library Quant Assay (Qiagen; QSTF-ILZ-F). NGS was performed on the Illumina Hi-Seq with a median on-target coverage of 701x.

### *Sequence Alignment and Analysis of Variants*

Raw sequencing data was aligned to Human Genome (build GRCH37.p13/hg19) reference [64] using BWA aligner(v0.7.10) [65]. Post-alignment data was passed through Picard Tools (V1.125) [66] to assess the alignment quality. Quality-controlled alignment data was employed to call the variants using an in-house variant caller, MDLVC, which scans through the alignment data for raw variants. Resulting raw variant calls were further applied with various filters including minimum base quality of q25, minimum base depth of 25, strand bias threshold, and allele frequency of  $\geq 5\%$ . In addition to the above filters, false positive variant calls arising due to the given sequencing run were

assessed, tracked, and filtered out using two negative controls (i.e. DNA isolated from normal, FFPE prostate tissue) sequenced in this study. Variant calls that were coding silent or that were designated as common in populations by dbSNP [67], EXaC [68], TCGA [69], and ClinVar [70] reference databases were excluded from analyses. ClinVar was used to determine pathogenicity of missense mutations [70]. Missense mutations that were pathogenic or likely pathogenic by ClinVar were used for analyses. High-confidence somatic variants were further annotated with information from COSMIC [71], Mutation Assessor, and cBioPortal [72]. Final variant calls were visualized and assessed further for validity using Integrated Genome Viewer (IGV) [73].

#### *ddPCR*

ddPCR for the *SPOP* gene's mutational status was performed as described previously [60]. All cfDNA was first PCR-amplified using Platinum SuperFi™ (Invitrogen) and the following primers (IDT; depending on the given *SPOP* mutation of interest): preAMP-Int6-F1 (GGCTTTGATCTGGTTTTTGCG) and preAMP-Ex7Int7-R1 (GAATACAAGGACTCACCTCG; for F125L mutation only) or preAMP-Int7-R1 (TCAGATCTGGGAACTGCTAG; for W131C and F133L mutations). The annealing temperatures for these primers were 60°C for preAMP-Int6-F1 and preAMP-Ex7Int7-R1 and 55°C for preAMP-Int6-F1 and preAMP-Int7-R1. The following primers (IDT) were used in the ddPCR: (1) For F125L: dd-SPOP-Int6Ex7-F1 (TTTTCCCCACCCAGAGAG) and dd-SPOP-Ex7-R3 (ATCAGGGAGAAGCCCGTTGG) (2) For W131C and F133L: dd-SPOP-Ex7-

F1 (CCAGAGAGTCAACGGGCAT) and dd-SPOP-Ex7-R1 (GCTTGTTCATCAGGGAGAAGC). Dual-labeled (FAM or HEX) fluorescent-quencher hydrolysis probes (IDT) were designed for *SPOP* mutations (F125L, W131C, and F133L) and their respective wild-type loci. The following are the probes that were used for each loci in this ddPCR (with the mutated amino acid in **bold**): (1) F125 region: SPOP-F125-WT (HEX: GGCATATAGGTTTGTGCAAGGCA) and SPOP-F125L-MUT1 (FAM: GGCATATAGG**TTGG**TGCAAGGCA) (2) F131 region: SPOP-W131-WT (HEX: TGCAAGGCAAAGACTGGGGATTCA) and SPOP-W131C-t-MUT1 (FAM: TGCAAGGCAAAGACT**GT**GGATTCA) or SPOP-W131C-c-MUT2 (FAM: TGCAAGGCAAAGACT**GCG**GGATTCA) (3) F133 region: SPOP-F133-WT (HEX: CAAAGACTGGGGATTCAAGAAATTC) and SPOP-F133L-MUT1 (FAM: CAAAGACTGGGGAT**TGA**AAGAAATTC). The following annealing temperatures for these primer and probe combinations are as follows: (1) 55°C (2) 58°C (3) 62°C for mutations W131C (t-mutant), W131C (with c-mutant) and F133L, respectively.

Wild-type male cfDNA was used as a control. The following gBlocks® Gene Fragments were designed (with mutated amino acids in **bold**) and ordered from IDT to act as additional controls for the ddPCR: (1) SPOP-Ex7-WT: 5'-TTCATACACTGACAAGTTGTGGCTTTGATCTGGTTTTTTCGTAACCTTAAATA TGACTTTTTTTTTTCCCCACCCCAGAGAGTCAACGGGCATATAGGTTTGTGCA AGGCAAAGACTGGGGATTCAAGAAATTCATCCGTAGAGATTTTCTTTTGGAT GAGGCCAACGGGCTTCTCCCTGATGACAAGCTTACCCTCTTCTGCGAGGTG

hood and according to the manufacturer's protocol. Total molecules were  
quantified by the QX200 Droplet Reader software.

## **Results**

### *Patient Cohort*

In total, 17 patients with localized PCa were enrolled prior to radical prostatectomy. Patient characteristics are summarized in Table 1.2. The median age at enrollment for the overall cohort was 62 years. The majority of patients were of the Caucasian/White racial background and were diagnosed with their primary PCa in 2013. All patients had a representative pre-surgery samples, while 4 patients (or 23.5% of patients) did not have a representative post-surgery sample. The median pre-surgery PSA level for the cohort was 8.1ng/mL and the median post-surgery PSA level for the cohort was undetectable.

The patient's primary PCa characteristics in this study are summarized in Table 1.3. Seven (or 41% of) localized PCa patients had a clinical stage of T1c. The median biopsy and pathological Gleason sums of this cohort were both equal to eight, while the range of the biopsy and pathological Gleason sums were both six to 10. Six (or 35% of) patients in this cohort had a pathological stage of

pT2 pN0. Only two (or 12% of) patients had positive lymph nodes. While over three-quarters of the patients had negative bone scans, the results of the bone scans for the remaining one-quarter of patients were not recorded in this study. After surgery, four patients (or 24% of patients) still had a positive surgical margin.

#### *Genetic Alterations in Localized PCa Patient Cohort*

It was discovered by NGS of primary tumor DNA that each of the 17 patients possessed multiple genetic alterations in their respective FFPE, radical prostatectomy samples. For simplification purposes, Table 1.4 only lists the one genetic alteration that was chosen for follow-up with ddPCR. Currently, a genetic alteration has not been chosen for pursuit by ddPCR in two (or 12%) of the patients. Twenty-seven percent (4/15) of the remaining mutations listed in Table 1.4 were annotated by ClinVar as pathogenic or likely pathogenic. Interestingly, five patients (or 29% of the total patients in this study) had the following *SPOP* missense mutations, all of which are found within the MATH domain of the protein: F125L, W131C, and F133L. While ClinVar annotated three of the *SPOP*-W131C and F133L mutations as pathogenic or likely pathogenic, it is important to note that a prior study demonstrated that *SPOP* mutations are not associated with worse outcomes, such as shorter length of time to biochemical recurrence, in PCa patients [27].

Two (2/17; 12%) additional patients had *TP53* mutations causing frameshifts of unknown clinical significance. Another two patients had *KMT2D*

mutations both of which were single nucleotide deletions. Only one (1/17; 6%) patient had a missense mutation in *KDM6A*. However, over 76% of the total read counts for this locus in this patient's NGS library contained this mutation, and so it is possible that this *KDM6A* missense mutation is germline. Interestingly, two patients had one mutation in the following mismatch repair genes: mutS homolog 2 (*MSH2*) and mutL homolog 1 (*MLH1*). While the missense mutation in *MSH2* is of unknown significance, the *MLH1* mutation is involved in splicing and is predicted to have pathogenic consequences [71]. One patient had a neutral missense mutation in *SCN11A* that was found in over 56% of the total read counts, meaning that this patient could also have a germline mutation. One patient had a splice site mutation in the *MED12* gene and another patient had a frameshift mutation in the Fanconi anemia complementation group M (*FANCM*) gene. The *FANCM* protein is involved in the DNA damage repair pathway, possibly even assisting *BRCA2* [74], however, it is unclear if the particular mutation found in this study's patient sample is of clinical relevance.

#### *Mutational Status of Patient cfDNA by ddPCR*

The ddPCR results for the cfDNA analyzed from four patients thus far can be viewed in Figure 1.2. From these results, it was determined that Patients 1, 6, and 9 are not positive for the anticipated *SPOP* mutations that were originally discovered in their primary tumor DNA by NGS. However, the *SPOP*-W131C mutation was found in Patient 14's cfDNA by ddPCR at very low levels. The frequency of this *SPOP*-W131C mutation in Patient 14 is 0.0002.

## Discussion and Future Directions

One limitation of this study is its small sample size (n=17). Thus, the percentages of patients who have a given genetic alteration in this study and the percentage of primary tumors that have the same genetic alteration in the previously mentioned studies available through cBioPortal (Figures 1.1 and 1.3) cannot be compared. For example, in this study five out of the 17 total subjects (29%) had *SPOP* mutations in their primary tumor DNA isolated from the FFPE, radical prostatectomy samples; however, it is estimated that only about 10% of primary tumors available on cBioPortal have genomic aberrations in the *SPOP* gene. If this study consisted of a larger number of consented patients, then the percentage of *SPOP* mutations may not have been so high.

Another limitation of this study is that it is currently in-progress as both aims are still being addressed. All plasma-derived cfDNA samples taken before radical prostatectomies for the remaining 13 patients are being assessed by ddPCR for the presence of each genetic alteration listed in Table 1.4. As for the four patients whose cfDNA was probed by ddPCR for the given *SPOP* mutations discovered by NGS, the mutations of interest were not detected in three of the patients thus far. Meanwhile, Patient 14 was confirmed to contain the mutation of interest in his cfDNA at extremely low levels. Before absolute conclusions can be drawn from these results, the remaining 13 patients' cfDNA samples need to be assessed by ddPCR for the chosen mutation of interest. In addition, all 17 plasma-derived cfDNA samples taken after radical prostatectomy still need to be

assessed by ddPCR. The completion of these ddPCRs is imperative for truly discerning whether or not plasma-derived cfDNA from primary PCa patients can be reliably utilized to detect genetic alterations at this early stage of the disease. Ultimately, this small study could discover potential biomarkers for the purpose of distinguishing between an indolent and aggressive PCa, thereby better predicting disease outcomes and treatment responses in patients with localized PCa.

## **Genetic Alterations Detected in Cell-free DNA are Associated with Enzalutamide and Abiraterone Resistance in Castration-resistant Prostate Cancer**

**\* This chapter has been submitted for publication and reprinted here:**

**Torquato S**, Pallavajjala A, Goldstein A, Toro PV, Silberstein JL, Lee J, Nakazawa M, Waters I, Chu D, Shinn D, Grogonski T, Hughes RM, Simons BW, Khan H, Feng Z, Carducci MA, Paller CJ, Denmeade SR, Kressel B, Eisenberger MA, Antonarakis ES, Trock BJ, Park BH, Hurley PJ. Genetic Alterations Detected in Cell-free DNA are Associated with Enzalutamide and Abiraterone Resistance in Castration-resistant Prostate Cancer.

## **Abstract**

*PURPOSE.* Androgen receptor (*AR*) gene alterations, including ligand-binding domain (LBD) missense mutations and copy number (CN) gain, as predictive markers of resistance to enzalutamide and abiraterone in men with metastatic castration-resistant prostate cancer (mCRPC) have yet to be fully established. The goal of this study was to validate *AR* gene alterations detected in cell-free DNA (cfDNA) as markers of enzalutamide and abiraterone resistance in mCRPC patients.

*METHODS.* Patients with mCRPC (n=62) were prospectively enrolled between 2014 and 2018. Blood was collected prior to therapies: enzalutamide (n=25), abiraterone (n=35), or concurrent enzalutamide and abiraterone (n=2) and at progression. Deep next-generation sequencing (NGS) was used to analyze cfDNA for sequence variants and CN status in *AR* and 46 additional cancer-associated genes. The primary endpoints were PSA response, progression-free survival (PFS), and overall survival (OS).

*RESULTS.* Elevated tumor-specific cfDNA (ctDNA) was associated with a worse PSA response (HR: 3.17; 95%CI: 1.11-9.05;  $P=0.031$ ), PFS (HR: 1.76; 95%CI: 1.03-3.01;  $P=0.039$ ), and OS (HR: 2.92; 95%CI: 1.40-6.11;  $P=0.004$ ). *AR* LBD missense mutations (HR: 2.51; 95%CI: 1.15-5.72;  $P=0.020$ ) were associated with a shorter PFS in multivariable models. *AR* CN gain was associated with a shorter

PFS; however, significance was lost in multivariable modeling ( $P=0.060$ ). Genetic alterations in tumor protein p53 (*TP53*; HR: 2.70; 95%CI: 1.27-5.72;  $P=0.009$ ) and phosphoinositide 3-kinase (PI3K) pathway defects (HR: 2.62; 95%CI: 1.12-6.10;  $P=0.026$ ) were associated with a worse OS.

**CONCLUSION.** These findings support that high ctDNA, *AR* LBD hotspot missense mutations, and, to a limited extent, *AR* CN gain are associated with a worse response to next-generation anti-androgen therapies and that ctDNA burden, *TP53* loss, and PI3K pathway defects are associated with worse OS in men with mCRPC.

## **Introduction**

Prostate cancer remains a leading cause of cancer-related death in US men due to the subset of patients who develop metastatic disease. Most patients with metastatic prostate cancer respond initially to contemporary androgen deprivation therapies (ADT), but eventually progress to mCRPC. Next-generation therapies targeting the androgen-AR axis, such as abiraterone and enzalutamide, have improved survival outcomes for men with mCRPC [1-4], but both primary and acquired resistance to these drugs continue to be a substantial clinical challenge. Thus, there is a need to identify robust biomarkers to guide therapy decisions for patients with mCRPC, especially given the availability of

various non-hormonal therapies (i.e. chemotherapy, immunotherapy, and bone-targeted therapy).

Resistance mechanisms to therapies targeting the androgen-AR axis are not fully understood; however, some forms of resistance likely involve *AR* gene alterations, including amplification and mutations. *AR* gene alterations are rare in primary prostate cancers with a reported incidence of less than 2% of cases [5-7]. In contrast, *AR* gene alterations are highly prevalent in mCRPC with a combined frequency of 50-60% [8-11], thereby, supporting their association with resistance to androgen-AR axis therapies [12, 13]. Moreover, amplification of *AR* occurs far more commonly than *AR* LBD missense mutations in mCRPC (approximately 50% vs. 15% of cases) with some cases exhibiting multiple *AR* alterations [10]. Thus, *AR* gene alterations may be relevant biomarkers for decision-making in clinical practice.

Metastatic tissue biopsies as a sole means to determine and follow changes in *AR* status is impractical, and thus cfDNA is gaining traction as a minimally invasive and easily obtainable tumor biopsy surrogate. Prior studies using cfDNA from the blood to evaluate the association of *AR* gene aberrations with resistance to abiraterone and enzalutamide are inconclusive [14-17]. Elevated *AR* levels in cfDNA as measured by CN gain [18, 19] and/or amplification [20], or detection of two or more *AR* mutations [20] have been associated with worse outcomes when men are treated with therapies such as abiraterone and enzalutamide. In contrast, neither *AR* CN gain nor *AR* LBD mutations were significantly associated with time to progression on abiraterone

and enzalutamide therapies in multivariate models [17]. Thus, the role of *AR* gene aberrations in mediating resistance to androgen-AR axis therapies has not been fully determined and definitive prospective studies are needed for clinical validation.

*AR* gene alterations are only detected in a subset of patients who have either primary or acquired resistance to androgen-AR axis therapies, thereby highlighting the need to determine other mechanisms that may mediate resistance. The *AR* splice variant, *AR-V7*, is associated with resistance to enzalutamide and abiraterone [21-23] and is also associated with increased *AR* CN [24]. In addition to *AR*, alterations in other genes such as *TP53*, phosphatase and tensin homolog (*PTEN*), and breast cancer gene 2 (*BRCA2*) are enriched in lethal prostate cancer [8-11]. Recent studies support that lineage plasticity from an AR-dependent to an AR-independent state through loss of *TP53* and retinoblastoma-associated protein 1 (*RB1*) mediates resistance to androgen-AR axis therapies [25-27]. Consistent with this, *TP53* defects have been shown to be associated with worse outcomes with abiraterone and enzalutamide therapies [17]. Similar to *TP53*, *PTEN* may promote a less AR-dependent state to mediate castrate-resistance [28-31]. The role of *BRCA2* and other homology-directed repair (HDR) genes in mediating resistance to enzalutamide and abiraterone has not been definitively determined. While it has been reported that truncating mutations in *BRCA2* and ataxia-telangiectasia mutated gene (*ATM*) are associated with a shorter time to progression on enzalutamide and abiraterone

[17], other studies indicate that HDR defects may be associated with a better response to therapy [32, 33].

The primary goal of this study was to validate *AR* LBD mutations and/or *AR* CN gain detected in ctDNA as predictive markers to enzalutamide and abiraterone resistance in patients with mCRPC. The secondary goal was to determine if mutations in other genes enriched in lethal prostate cancer such as *TP53*, *PTEN*, and *BRCA2* were associated with response to enzalutamide and abiraterone. In this study, high ctDNA burden was significantly associated with PSA response, PFS, and OS. Study findings also validate that *AR* LBD mutations are significantly associated with a shorter PFS, even after controlling for factors such as ctDNA burden. Pre-therapy *AR* CN gain was significantly associated with both a shorter PFS and a worse OS, but lost significance when controlled for ctDNA burden. *TP53* loss and defects in the PI3K pathway were both associated with worse OS.

## **Results**

### *Patient Cohort*

Patient characteristics are summarized in Table 2.1. Pre-therapy PSA, PSA response, and PFS were not significantly different between patients on abiraterone and enzalutamide (Table 2.1; Figure 2.1A-C). Approximately one-quarter of patients had prior abiraterone or enzalutamide. Prior abiraterone or

enzalutamide was not significantly associated with PSA response ( $P=0.146$ ), PFS ( $P=0.620$ ) or OS ( $P=0.284$ ) (Tables 2.2 and 2.3; Figure 2.1D). ClinVar-annotated pathogenic or likely pathogenic mutations and/or CN alterations [34] were detected in cfDNA from 89% of patients prior to therapy initiation and in 92% of patients at progression (Figures 2.2A-D and 2.3).

### *ctDNA*

Total cfDNA concentration prior to therapy was associated with PSA ( $P=0.002$ ; Figure 2.4A). Deep NGS was used to analyze cfDNA for CN variation and mutations in 47 cancer-associated genes (Table 1.1). Nearly all patients (61/62) had detectable CN variation(s) and/or mutation(s) with an allelic frequency above the 1% cutoff (Figure 2.2B-C). High allelic fractions of ctDNA have been associated with poor prognosis [14, 17, 20]. High ctDNA burden was detected in approximately 44% of patients prior to therapy. High ctDNA burden was significantly associated with a worse PSA response (OR: 3.17; 95%CI: 1.11-9.05;  $P=0.031$ ) by logistic regression analyses (Table 2.2). High ctDNA burden was associated with a shorter median time to progression (14.0 weeks vs. 34.0 weeks;  $P=0.022$ ) and a shorter PFS (HR: 1.76; 95% CI: 1.03-3.01;  $P=0.039$ ) using proportional hazards modeling (Table 2.3; Figure 2.5A). High ctDNA burden was also significantly associated with a shorter median survival (62.7 weeks vs. 134.9 weeks;  $P=0.003$ ) and a worse OS (HR: 2.92; 95%CI: 1.40-6.11;  $P=0.004$ ) using proportional hazards modeling (Table 2.3; Figure 2.6A). Other clinical variables such as prior abiraterone or enzalutamide therapy, PSA, age,

and visceral metastases were not significantly associated with PSA response, PFS, or OS in univariate analyses (Tables 2.2 and 2.3).

## *AR*

Prior studies evaluating the associations between *AR* gene alterations, including CN gain and LBD missense mutations, with therapeutic outcomes are conflicting [14, 15, 17-20, 35]. *AR* CN gain was detected in approximately half of patients prior to therapy and at progression (Figures 2.2C-D and 2.3; Table 2.4). *AR* CN gain was not significantly associated with PSA response ( $P=0.119$ ; Table 2.2; Figure 2.5B), but was associated with a shorter median time to progression (16.1 weeks vs. 34.0 weeks;  $P=0.013$ ) and a shorter median survival (62.7 weeks vs. 144.9 weeks;  $P=0.002$ ) (Figures 2.5C and 2.6B). Using proportional hazards modeling, PFS (HR: 2.07; 95%CI: 1.20-3.57;  $P=0.009$ ) and OS (HR: 3.26; 95%CI: 1.52-7.11;  $P=0.002$ ) were shorter in patients with *AR* CN gain; however, significance was lost upon inclusion of ctDNA burden in multivariable modeling (Figures 2.5C and 2.6B; Table 2.3).

Pathogenic *AR* LBD missense mutations were detected in cfDNA from 13% of patients prior to therapy initiation and in an additional 15% of evaluable patients at progression who were *AR* LBD missense mutation-negative prior to therapy (Figures 2.2C-D and 2.5D; Table 2.5). Using logistic regression analyses, pre-therapy pathogenic *AR* LBD missense mutations neared significance for a worse PSA response rate ( $P=0.072$ ; Table 2.2). Pre-therapy pathogenic *AR* LBD missense mutations were significantly associated with a

worse  $\geq 30\%$  decline in PSA (OR: 6.00; 95%CI: 1.10-32.76;  $P=0.039$ ; Table 2.2; Figure 2.5E), that remained significant when controlled for other factors including prior abiraterone or enzalutamide therapy ( $P=0.048$ ), pre-therapy PSA ( $P=0.044$ ), or ctDNA burden ( $P=0.039$ ) in multivariable logistic regression analyses (Tables 2.2 and 2.5).

Median time to progression was significantly shorter in patients who had an *AR* LBD missense mutation than in *AR* LBD mutation-negative patients (11.4 weeks vs. 28.7 weeks;  $P=0.021$ ; Figure 2.5F). Using proportional hazards modeling, *AR* LBD missense mutations detected prior to therapy were significantly associated with a shorter time to progression (HR: 2.39; 95%CI: 1.11-5.14;  $P=0.026$ ) even when controlled for ctDNA burden ( $P=0.020$ ; Table 2.3). However, *AR* LBD mutations were not significantly associated with a worse OS ( $P=0.364$ ; Table 2.3).

*AR* CN gain and *AR* LBD missense mutations were not mutually exclusive in cfDNA (Figure 2.2C). Collective *AR* alterations, including CN gain and LBD missense mutations, were significantly associated with a shorter PFS and OS, but significance was lost upon inclusion of ctDNA burden in multivariable modeling (Table 2.3).

Interestingly, two *AR* mutations at different allelic frequencies (T878A at 9.4% and L702H at 1.5%) were detected in one patient progressing on abiraterone plus prednisone who also had *AR* CN gain (Figure 2.2C; Table 2.4). Studies support that the *AR* L702H mutation mediates an acquired response to glucocorticoids thereby providing rationale to switch from prednisone to

dexamethasone [14, 20, 36]. In support of this notion, replacement of prednisone with dexamethasone resulted in a greater than 80% PSA decline for this patient (Figure 2.4B).

### *TP53 and RB1*

Genetic alterations in *TP53* are highly enriched in lethal prostate cancer [8-11]; and have recently been shown to be associated with worse PFS and OS in patients treated with abiraterone and enzalutamide [17]. *TP53* was highly altered in patients' cfDNA (Figures 2.2C-D and 2.6C); however, *TP53* defects (pathogenic mutations and/or CN loss) were not associated with PSA response ( $P=0.602$ ) or PFS ( $P=0.314$ ; Tables 2.2 and 2.3). Conversely, median OS was shorter in patients with a *TP53* defect compared to patients without a detectable *TP53* defect (68.1 weeks vs. 134.9 weeks;  $P=0.001$ ; Figure 2.6D). Using proportional hazards modeling, *TP53* defects were associated with worse OS (HR: 3.19; 95%CI: 1.53- 6.64;  $P=0.002$ ) that remained significant after adjusting for clinical variables including ctDNA ( $P=0.009$ ), prior abiraterone or enzalutamide ( $P=0.003$ ), or PSA ( $P=0.001$ ) (Tables 2.3 and 2.6). Patients with both *TP53* and *RB1* defects had an even shorter median OS compared to patients with a *TP53* defect alone or to patients with intact *TP53* (35.4 weeks vs. 77.4 weeks vs. 157.7 weeks;  $P<0.001$ ; Figure 2.6E). *TP53* defects in conjunction with *RB1* defects were associated with worse OS (HR: 4.50; 95%CI: 1.79-11.28;  $P=0.001$ ) that remained significant after adjusting for ctDNA burden ( $P=0.002$ ) (Table 2.3).

### *PI3K and wingless-type MMTV integration site (WNT) Pathways*

PI3K pathway defects involving genetic alterations in *PTEN* (CN loss and/or truncating mutations) and phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha (*PIK3CA*; CN gain) were detected in nearly one-quarter of patients prior to therapy (Figure 2.2C-D). Patients with PI3K pathway defects prior to therapy had a significantly shorter median survival (49.4 weeks vs. 134.9 weeks;  $P < 0.001$ ) and a worse OS (HR: 3.64; 95%CI: 1.69-7.86;  $P = 0.001$ ), even after controlling for ctDNA burden ( $P = 0.026$ ) (Figure 2.6F; Tables 2.3 and 2.7). PI3K pathway alterations were also associated with a worse PSA response that remained significant after adjusting for ctDNA burden (HR: 8.53; 95%CI: 2.09-34.81;  $P = 0.003$ ). WNT pathway defects involving genetic alterations in adenomatous polyposis coli (*APC*; CN loss and truncating mutations) and beta-catenin (*CTNNB1*; CN gain and pathogenic missense mutations) were detected in 15% of patients prior to therapy (Figure 2.2C-D). WNT pathway defects were associated with a worse OS (HR: 2.92; 95%CI: 1.28-6.68;  $P = 0.011$ ) using proportional hazards modeling; however, significance was lost after controlling for ctDNA burden ( $P = 0.051$ ) (Figure 2.6G; Table 2.3).

### *BRCA1, BRCA2, and ATM*

Men with lethal prostate cancer are more likely to have germline mutations in DNA repair genes [37, 38]; however, the association of *BRCA1*, *BRCA2*, *ATM*, and other HDR gene defects with response to androgen-AR axis therapies such as abiraterone and enzalutamide is conflicting [17, 32, 33]. Approximately one-

third of patients had germline and/or somatic deleterious mutations in or CN loss of *BRCA1*, *BRCA2*, or *ATM* prior to therapy with some patients having more than one mutation (Figures 2.2C-D and 2.7A-C), a prevalence that is consistent with published literature [17]. Collective ClinVar deleterious missense mutations, truncating mutations, and/or CN loss in *BRCA2*, *BRCA1*, or *ATM* were not significantly associated with PSA response ( $P=0.417$ ), PFS ( $P=0.855$ ), or OS ( $P=0.326$ ) (Tables 2.2 and 2.3). Analysis of truncating mutations in *BRCA1*, *BRCA2*, and *ATM* did not improve prognostic significance.

## Discussion

Liquid biopsies using cfDNA as a tumor analyte are rapidly being developed for cancer diagnostics of solid tumors [39-41]. When obtained concurrently, plasma-derived cfDNA is highly concordant with tissue biopsies from prostate [42] and other [43] cancers for tumor-specific genetic alterations. Liquid biopsies using cfDNA are advantageous over traditional tissue biopsies for numerous clinical reasons including ease of accessibility and the ability to provide a global “snapshot” of the mutational landscape. Furthermore, cfDNA better recapitulates tumor heterogeneity than single-site biopsies and can be used sequentially to monitor cancer dynamics. Clinical development of cfDNA has the potential to advance prostate cancer precision medicine [44].

Mechanisms of resistance to abiraterone and enzalutamide likely involve alterations to androgen-AR axis signaling. Prior studies have indicated that collective genetic aberrations to *AR*, including CN gain and mutations, are associated with worse outcomes in patients on abiraterone or enzalutamide therapies [14, 15]. The value of *AR* LBD mutations alone as a predictive marker for response to enzalutamide and abiraterone in patients with mCRPC has yet to be fully established. A prior study showed that mCRPC patients harboring two or more *AR* mutations had worse outcomes on enzalutamide [20]. An additional retrospective study showed that *AR* mutations (L702H and T878A) were associated with shorter PFS and OS in post-docetaxel mCRPC patients on enzalutamide or abiraterone [19]. In a recently reported prospective study, missense mutations in the *AR* LBD were not associated with time to progression on abiraterone or enzalutamide therapies in treatment naïve mCRPC patients [17]. We found that ClinVar pathogenic/likely pathogenic *AR* LBD missense mutations detected in cfDNA prior to enzalutamide and abiraterone therapies were significantly associated with a shorter time to progression that was independent of PSA, prior therapy, or ctDNA fraction. Discrepancies between study findings may be due to several factors including prior therapy, study therapy, specific *AR* LBD mutation, *AR* amplification, and disease burden. Due to their low prevalence, *AR* LBD missense mutations are often combined for analyses; however, studies support that *AR* LBD missense mutations have distinct functional properties that mediate therapy resistance including ligand promiscuity and agonistic activity [25, 36]. Future prospective studies and meta-

analyses will be necessary to determine fully the roles individual mutations in drug resistance. Overall, our findings support that the presence or absence of pathogenic *AR* LBD missense mutations detected in cfDNA by NGS may afford clinical utility as predictive markers of response to enzalutamide and abiraterone therapies; however, large-scale, multi-center prospective validation is necessary to determine their biomarker potential.

Recent reports also indicate that *AR* CN gain as a single marker is associated with worse outcomes in mCRPC patients on abiraterone and enzalutamide [19, 20]. A retrospective study of three biomarker protocols reported that *AR* CN gain was significantly associated with worse PFS and OS in men treated with enzalutamide or abiraterone for mCRPC [19]. A similar report showed that *AR* CN gain was associated with significantly worse PSA response and PFS in patients on enzalutamide [20]. Consistent with prior reports, our study showed that *AR* CN gain was significantly associated with shorter PFS and OS. However, significance was lost when controlling for high ctDNA burden in multivariable modeling. Consistent with our findings, a recent report also indicates that *AR* CN gain is not significantly associated with time to progression in multivariable modeling [17]. Clearly, further prospective studies are needed to assess the clinical utility of *AR* CN gain as a predictive biomarker for therapeutic response to enzalutamide and abiraterone in patients with mCRPC.

In our study, *TP53* and PI3K pathway defects were associated with worse OS. Deregulation of these pathways likely mediates resistance to androgen-AR axis therapies. Concurrent *TP53* and *RB1* defects are highly enriched in AR-

independent neuroendocrine mCRPC compared to adenocarcinoma mCRPC [45]. Combined *TP53* and *RB1* loss has been shown to promote lineage switching from an AR-dependent to an AR-independent state [25-27], and consequent resistance to AR-targeted therapies. Similar to *TP53*, genetic alterations in *PTEN* are enriched in mCRPC compared to metastatic castration-sensitive prostate cancer and localized prostate cancer [11]. Studies suggest that *PTEN* loss may mediate castration resistance by downregulating AR [28-31], thereby supporting a rationale for combined inhibition of PI3K and AR in *PTEN*-deficient mCRPCs [46, 47].

The association of pathogenic mutations in HDR genes, such as *BRCA1*, *BRCA2*, and *ATM*, with response to abiraterone and enzalutamide therapy is conflicting. A recent clinical trial in patients with mCRPC suggested that genetic alterations in HDR genes detected by NGS of metastatic biopsy tissue may be associated with longer PFS when on abiraterone therapy [32]. Concordant findings were observed in a second study that suggested that mCRPC patients harboring a germline *BRCA1/2* or *ATM* mutation may also have improved outcomes to abiraterone and enzalutamide [33]. In contrast, a recent study showed that truncating mutations in *BRCA2* and *ATM* detected in cfDNA were associated with a shorter time to progression on abiraterone and enzalutamide therapies in treatment naïve mCRPC patients [17]. In our study, collective somatic and germline genetic alterations, including ClinVar pathogenic mutations and/or CN loss, in *BRCA1*, *BRCA2*, and *ATM* were not associated with PSA response, PFS, or OS. Truncating mutations alone in *BRCA1*, *BRCA2*, and *ATM*

were also not associated with worse outcomes to enzalutamide and abiraterone. Association differences may reflect variables such as sample size, prior treatment status, disease burden, disease heterogeneity, somatic vs. germline, and single vs. dual loss. Certainly, further prospective investigation is needed to determine the clinical significance of HDR mutations as predictive markers to abiraterone and enzalutamide therapies.

In the current study, many patients had detectable alterations that could serve as potential therapeutic targets. Prior studies have shown that mCRPC patients with either germline or somatic mutations in HDR genes had significant responses to olaparib [48] and to abiraterone plus veliparib [32]. Over one-quarter of patients in our study had a deleterious germline or somatic *BRCA1*, *BRCA2*, or *ATM* mutation detected prior to therapy or at progression suggesting that these patients may benefit from therapies targeting poly (ADP-ribose) polymerase (PARP) or platinum-based chemotherapy [32, 48, 49]. In addition, immunotherapy trials have been largely unsuccessful in men with mCRPC [50], however, rare responders have been reported [51]. A seminal clinical trial showed that microsatellite instable cancers caused by mismatch repair (MMR) gene deficiency were sensitive to PD-1 blockade perhaps due to the formation of neoantigens resulting from increased mutational burden [52]. Inactivation of MMR genes and elevated mutational burden have been detected in some men with aggressive prostate cancers [37, 53, 54]. One patient in our study had a detectable noncanonical MMR gene mutation in his cfDNA and a correspondingly high mutational burden suggesting that he may be an ideal candidate for

checkpoint immunotherapy. This study supports that cfDNA may be a useful analyte for directing clinical decisions in prostate cancer precision medicine.

Several limitations to our study exist. Notably, the small sample size precluded multivariable analyses incorporating more than two variables and analyses by therapy subgroup. Larger prospective studies will be needed to validate our findings. Samples were obtained from two hospitals, and future prospective studies would benefit from inclusion of a larger number of institutions. A final limitation was our inability to evaluate *AR* splice variants, including *AR-V7*, due to the requirement of circulating tumor cells or whole-blood RNA; presence of *AR-V7* is certainly another established mechanism of primary and acquired resistance to next-generation hormonal therapies [21-23]. Future studies should aim to simultaneously analyze the full complement of *AR* aberrations, including gene mutations, amplifications, genomic structural rearrangements, and mRNA splice variants from a single liquid biopsy.

In summary, our findings indicate ctDNA burden is highly associated with worse outcomes to enzalutamide and abiraterone. In addition, pathogenic *AR* LBD missense mutations are associated with a shorter time to progression on abiraterone and enzalutamide in men with mCRPC. *TP53* loss, especially in the context of concurrent *RB1* defects, and PI3K pathway defects are associated with a worse OS. These studies provide the rationale for larger prospective multi-institutional studies to further assess the clinical utility of integrating genetic alterations detected in cfDNA for optimal management of metastatic prostate cancer.

## Materials and Methods

### *Patients*

This prospectively collected biomarker study was approved by the Johns Hopkins Medicine Institutional Review Board (IRB). All patients provided written informed consent prior to enrollment. Eligibility criteria included patients diagnosed with mCRPC who were about to begin either abiraterone or enzalutamide therapy. Seventy patients were prospectively enrolled between September 2014 and June 2017 at the Johns Hopkins Hospital (Baltimore, MD) and Sibley Memorial Hospital (Washington, D.C.) and followed through April 2018. Patients had histologically confirmed prostate adenocarcinoma, progressive disease despite ADT, and documented metastatic disease by computed tomography (CT) or bone scan with technetium-99m-labeled methylene diphosphonate. Of the 70 enrolled patients with mCRPC who were about to begin either abiraterone or enzalutamide therapy, three patients were excluded due to concurrent treatment with other therapies (Veliparib or Docetaxel). Five eligible patients were excluded due to the absence of clinical follow-up data. Blood and clinical follow-up data were obtained for the remaining 62 patients. Blood was collected prior to initiation of therapy for all patients with most pre-therapy samples collected within one week prior to start of therapy (median collection day was on the day of therapy initiation). Patients were treated with enzalutamide (n=25), abiraterone + prednisone (n=35), or concurrent enzalutamide plus abiraterone + prednisone (n=2).

### *Study Endpoints*

Study endpoints were PSA response, PFS, and OS. PSA response was defined by a  $\geq 50\%$  decline in PSA from pre-therapy baseline PSA. A  $\geq 30\%$  decline in PSA from pre-therapy baseline PSA was also evaluated. Progression was defined by an increase in PSA by  $\geq 25\%$  above the baseline or nadir PSA, radiographic progression, or death from prostate cancer. PSA increase by  $\geq 25\%$  above the baseline or nadir PSA was confirmed by a subsequent PSA increase, radiographic progression, death from prostate cancer, or physician-determine change of therapy. PFS was defined by the time to the first of the following events: an increase in PSA by  $\geq 25\%$  compared to baseline or nadir PSA, radiographic progression, or death from prostate cancer. Blood was also collected following PSA increase from nadir prior to change in therapy for 26 of the 35 patients who had a decrease in PSA following therapy and then progressed as determined by an increase in PSA by  $\geq 25\%$  above the baseline or nadir PSA, radiographic progression, or death from prostate cancer.

### *Plasma and cfDNA Isolations from Blood Samples*

Three, 10mL blood samples were collected in Streck BCT tubes prior to therapy initiation and if applicable, at progression. Please refer to the same subsection in Chapter 1's Materials and Methods section for all remaining protocol details.

## *Deep NGS*

NGS libraries were prepared from cfDNA similarly to the protocol in the same subsection of Chapter 1's Materials and Methods section. Between 0.5 and 40.0ng of cfDNA was used for library generation. Additional differences between these study protocols include the following: samples were PCR-amplified using Qiagen's GeneRead™ DNaseq Panel PCR Reagent V2 for 18-22 cycles depending on input cfDNA concentration and only the GeneRead™ Adapter I Set A 12-plex was used to construct all libraries. Prepared libraries were then quantified using two QIAseq™ Library Quant Assay Kits (Qiagen; QSTF-ILZ-F or NGTF-ILZ-R). Lastly, the median on-target coverage for these cfDNA libraries was 6,631x.

## *Sequence Alignment and Analysis of Variants*

Please refer to the same subsection in Chapter 1's Materials and Methods section for all protocol details. Major differences between these study protocols include the following: the filter applied for allele frequency was  $\geq 1\%$  with the exception of *AR* which had a previously validated allele frequency threshold of  $\geq 0.5\%$  [16]. Additionally, false positive variant calls arising due to the given sequencing run were assessed, tracked, and filtered out using 11 negative controls sequenced in this study. For patients with allelic fractions of ClinVar [54] pathogenic or likely pathogenic *BRCA1* or *BRCA2* mutations that were  $\geq 20\%$ , germline information was obtained through clinical records or by sequencing germline leukocyte DNA obtained from isolated buffy coat.

### *CN Variation*

NGS-based CN detection was performed using an in-house developed algorithm, TMM-CNV and third-party tool, CNVKit [55]. TMM-CNV calculates trimmed mean and corresponding two standard deviations from mean relative coverage depths obtained for the sample and a mean of multiple references including sequence of 9 healthy controls (pool of controls). Data distribution at the gene-level was used to apply a trimmed mean of 0.2, 0.1, and corresponding standard deviation to calculate and set the lower and upper thresholds for calling focal deletions and focal amplifications, respectively. For autosomes a  $\log_2$  value of mean relative coverage depth between sample and pool of controls was used, whereas for chromosome X, logarithmic value of mean relative coverage depth between sample and pool of controls was used. Final CN calls between TMM-CNV and CNVKit were compared for consensus. Conservative thresholds based on heterozygous SNP fractions of control cfDNA were used to call CN gain and deletion. Given that a targeted gene panel was used for sequencing and tumor cellularity varies in cfDNA sequencing, two thresholds were applied to detect copy gains and losses. CN gain for autosomes was defined by a  $\log_2$  ratio of mean relative sequencing coverage at the gene level  $\geq 0.4$  and  $\geq 1.2$ . CN loss for autosomes was defined by a  $\log_2$  ratio of mean relative sequencing coverage at the gene level  $\leq -0.4$  and  $\leq -0.6$ . For chromosome X, CN gain was defined by a logarithmic ratio of mean relative sequencing coverage at the gene level  $\geq 0.7$  and  $\geq 1.2$ , and CN loss was defined by a logarithmic ratio of mean relative sequencing coverage at the gene level  $\leq -0.4$  and  $\leq -0.6$ .

### *Estimation of ctDNA Fraction*

Estimation of high versus low ctDNA fraction was based upon both mutant allele fraction (MAF) and CN alterations. The fraction of ctDNA (% ctDNA) was estimated based upon the highest autosomal variant allele fraction. ctDNA burden was dichotomized into high and low for statistical analyses. Patients with low ctDNA burden had a ClinVar pathogenic missense or truncating MAF < 7%. Conversely, patients with a high ctDNA burden had a ClinVar pathogenic missense or truncating MAF  $\geq$  7% and/or a CN loss  $\leq$  -0.55 and/or a CN gain  $\geq$  1.0.

### *Statistical Analyses*

Sample size estimate of 60 informative patients was calculated prior to study initiation. Power and confidence bounds were calculated using PASS 11 (NCSS Software). Chi-squared tests and logistic regression were used to determine associations between genomic status and PSA response. Kaplan-Meier methods and log-rank tests were used to estimate survival functions. Cox proportional-hazard modeling was used to estimate PFS and OS. Due to small sample size, clinical variables were dichotomized. PSA was dichotomized at 20ng/mL based on the median PSA of 19.3ng/mL. Age was dichotomized at 72 years based on the median age of 71.5 years. Prior abiraterone and enzalutamide was dichotomized as yes or no, visceral metastases was dichotomized as yes or no, and ctDNA burden was dichotomized as low or high. Multivariable models included only two variables to reduce the likelihood of

overfitting. Statistical analyses were performed using STATA SE/15.1, and GraphPad Prism 5 was used for figure generation.

**Figure 2.1.** PSA response and PFS were similar between patients on abiraterone + prednisone and patients on enzalutamide. (A) Waterfall plot of best PSA response for patients receiving abiraterone + prednisone therapy (n=35) as determined by best percentage fold change in PSA. (B) Waterfall plot of best PSA response for patients receiving enzalutamide therapy (n=25) as determined by best percentage fold change in PSA. Chi-squared analysis of PSA response in patients receiving abiraterone + prednisone compared to patients on

enzalutamide ( $P=0.583$ ). (C) Kaplan-Meier method and log-rank test to determine median time to progression for patients who were treated with abiraterone + prednisone ( $n=35$ ) compared to patients who were treated with enzalutamide ( $n=25$ ) therapy (26.1 weeks vs. 24.7 weeks;  $P=0.645$ ). (D) Kaplan-Meier method and log-rank test to determine median time to progression for patients who had prior abiraterone + prednisone or enzalutamide therapy ( $n=15$ ) compared to patients who were abiraterone + prednisone and enzalutamide naïve ( $n=47$ ) (17.9 weeks vs. 26.0 weeks;  $P=0.660$ ).

**Figure 2.2.** Genetic alterations detected in cfDNA prior to therapy and best PSA response. (A) Waterfall plot of best PSA response for all patients (n=62) following therapy as determined by best percentage fold change in PSA. (B) Total number of protein altering genetic changes in 47 genes detected by NGS of cfDNA from 62 patients prior to abiraterone and enzalutamide therapy. (C) Genetic alterations (CN status, ClinVar pathogenic/likely pathogenic missense and germline mutations, and truncating mutations) in 47 genes detected by NGS of cfDNA from 62 patients prior to abiraterone and enzalutamide therapy in order of best PSA response. (D) The total number of genetic alterations (CN and mutations) in 47 genes detected by NGS of cfDNA from 62 patients prior to abiraterone and enzalutamide therapy.

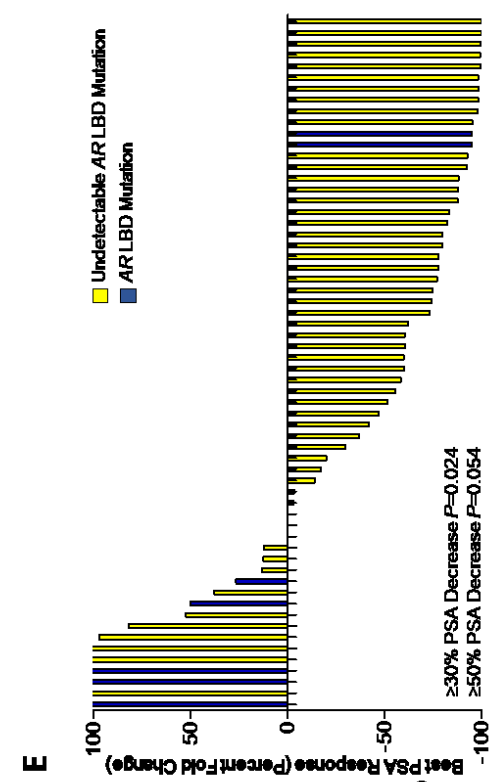

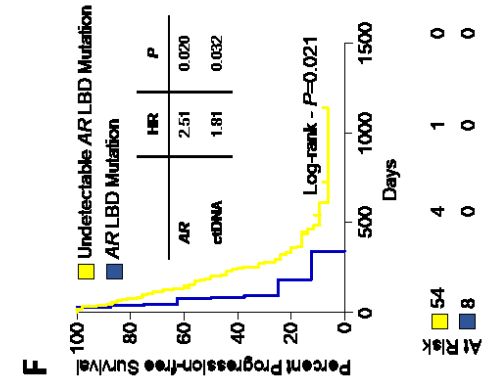

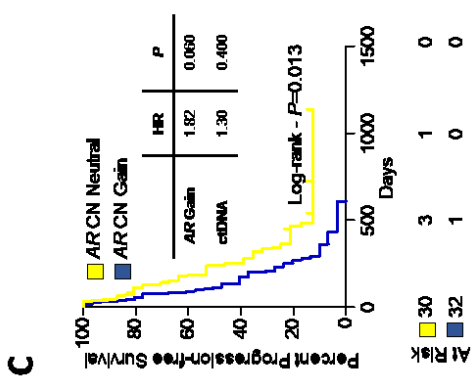

**Figure 2.3.** Genetic alterations detected in cfDNA following progression. Genetic alterations (CN status, ClinVar pathogenic/likely pathogenic missense and germline mutations, and truncating mutations) in 47 genes detected by NGS of

cfDNA from 26 patients following progression on abiraterone + prednisone or enzalutamide therapy.

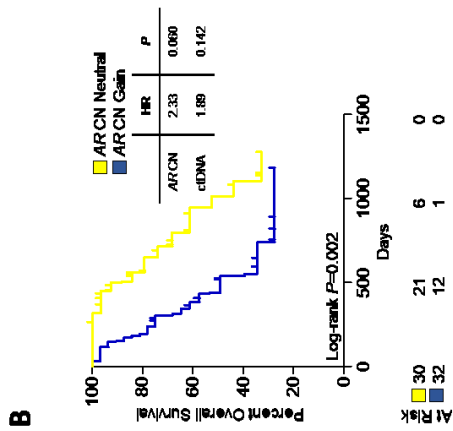

**Figure 2.4.** Pre-therapy PSA is associated with cfDNA concentration prior to therapy and a patient's PSA changes while progressing on treatment. (A) Pre-therapy PSA is associated with cfDNA concentration prior to therapy as determined using Pearson correlation ( $r=0.40$ ;  $P=0.002$ ). Pre-therapy PSA was compared with the amount of cfDNA isolated per 1.5mL plasma prior to therapy. (B) PSA for a patient progressing on abiraterone + prednisone with a detectable AR L702H mutation and then switched to abiraterone + dexamethasone.

**Figure 2.5.** PFS: pathogenic *AR* LBD mutations are associated with a shorter time to progression. (A) Kaplan-Meier method and log-rank test to determine median time to progression for patients who had high vs. low ctDNA prior to therapy. (B) Waterfall plot of best PSA response for all patients (n=62) following therapy as determined by best percentage fold change in PSA. *AR* CN gain determined by deep NGS of cfDNA prior to therapy. Chi-squared analyses for a  $\geq 30\%$  and  $\geq 50\%$  PSA decrease. (C) Kaplan-Meier method and log-rank test to determine median time to progression for patients who were positive vs. negative for *AR* CN gain prior to therapy. The association of *AR* LBD mutations with PFS controlled for ctDNA burden using multivariable proportional hazards modeling. (D) Gene schematic illustrating pathogenic *AR* LBD mutations detected by targeted NGS of cfDNA prior to abiraterone and enzalutamide therapies (NTD=N-terminal domain, DBD=DNA binding domain). (E) Waterfall plot of best PSA response for all patients (n=62) following therapy as determined by best percentage fold change in PSA. *AR* LBD mutations determined by deep NGS of cfDNA prior to therapy. Chi-squared analyses for a  $\geq 30\%$  and  $\geq 50\%$  PSA decrease. (F) Kaplan-Meier method and log-rank test to determine median time to progression for patients who were positive vs. negative for *AR* LBD mutations prior to therapy. The association of *AR* LBD mutations with PFS controlled for ctDNA burden using multivariable proportional hazards modeling.

**Figure 2.6.** OS: *TP53* and PI3K pathway defects are associated with worse OS. (A) Kaplan-Meier method and log-rank test to determine median OS for patients who had high vs. low ctDNA prior to therapy. (B) Kaplan-Meier method and log-rank test to determine median OS for patients who had *AR* CN gain prior to therapy. Association of *AR* CN gain with OS controlled for ctDNA burden using multivariable proportional hazards modeling. (C) Gene schematic illustrating deleterious *TP53* mutations detected by deep NGS of cfDNA prior to abiraterone and enzalutamide therapies and at disease progression while on therapy (P53T=P53 transactivation motif, P53=P53 DNA-binding domain, P53Tetra=P53 tetramerization motif). (D) Kaplan-Meier method and log-rank test to determine median OS for patients who had *TP53* defects (CN loss and or ClinVar pathogenic/likely pathogenic mutations) prior to therapy. Association of *TP53* defects with OS controlled for ctDNA burden using multivariable proportional hazards modeling. (E) Kaplan-Meier method and log-rank test to determine median OS for patients who had both *TP53* and *RB1* defects compared to patients who had *TP53* defects but were *RB1* intact (CN loss and or ClinVar pathogenic/likely pathogenic mutations) prior to therapy. Association of dual *TP53* and *RB1* defects with OS controlled for ctDNA burden using multivariable proportional hazards modeling. (F) Kaplan-Meier method and log-rank test to determine median OS for patients who had PI3K pathway defects (CN loss and/or truncating mutations in *PTEN* and/or CN gain of *PIK3CA*) prior to therapy. Association of PI3K defects with OS controlled for ctDNA burden using multivariable proportional hazards modeling. (G) Kaplan-Meier method and log-

rank test to determine median OS for patients who had WNT pathway defects (CN loss and/or truncating mutations in *APC* and/or CN gain and/or pathogenic missense mutations in *CTNNB1*) prior to therapy. Association of WNT defects with OS controlled for ctDNA burden using multivariable proportional hazards modeling.

**Figure 2.7.** Mutations detected in *BRCA1*, *BRCA2*, and *ATM* prior to therapy and at progression. A-C, Gene schematics illustrating deleterious germline and somatic mutations in (A) *BRCA2* (B=BRC repeats, Helical=helical domain, Oligo=oligonucleotide-binding domain, T=tower domain), (B) *BRCA1* (R=Ring finger domain, Serine=Serine rich domain associated with BRCT, BRCT=BRCA1 C terminus domain) and (C) *ATM* (TAN=Telomere length maintenance and DNA damage repair, FAT=FAT domain, PI3,4K=Phosphatidylinositol 3- and 4-kinase, FC=FATC domain) and as detected by deep, targeted NGS of cfDNA prior to abiraterone + prednisone and enzalutamide therapies and at progression while on therapy.

## Isogenic Modeling of Androgen Receptor Ligand-binding Domain Mutations

## Introduction

### *The Androgen Receptor (AR)*

The AR is a member of the steroid and nuclear receptor superfamily [1, 2] and is mainly expressed in androgen-target tissues, such as prostate, skeletal muscle, and liver [3]. AR functions as an intracellular transcriptional factor and is regulated by the binding of its ligands: androgens, such as testosterone (T) and 5-alpha-dihydrotestosterone (DHT). Androgen-AR interactions initiate conformational changes of the receptor such that receptor-protein and receptor-DNA interactions are affected and the transcription of androgen-responsive genes can commence [2]. In utero, the AR is responsible for male sexual differentiation, and during adolescence, it plays a role in male pubertal changes. In adult males, androgen-AR interactions are involved in spermatogenesis, muscle mass maintenance, and libido [4, 5].

The human *AR* gene is located on the X chromosome, contains eight exons, and encodes a protein that is 920 amino acids long [6, 7]. The three main functional domains of AR are the N-terminal domain (NTD, exon 1), DNA-binding domain (DBD, exons 2-3), and ligand-binding domain (LBD, exons 4-8) (Figure 3.1). The protein's hinge region (exon 4) is located between the DBD and LBD. The nuclear localization signal (NLS, exons 3-4) spans across the DBD and hinge region. AR has two transactivation functions. The N-terminal activation function 1 (AF1) is not conserved across other steroid receptors, and the C-

terminal activation function (AF2) is ligand-dependent and more conserved in sequence across other steroid receptors [8].

When AR is not bound to an agonist, it is mainly located in the cytoplasm, where its LBD associates with a complex of heat shock proteins (HSPs) [9]. Once a ligand or agonist binds to the receptor, AR dissociates from the HSPs and undergoes a series of conformational changes, including dimerization, phosphorylation, and nuclear translocation. Once in the nucleus, the ligand-activated AR can bind to an androgen response element (ARE), which is located in the promoter or enhancer region of AR-targeted genes. ARE-bound ARs can also recruit other transcription co-regulators (such as co-activators and co-repressors) [10] and transcriptional machinery [11], all of which further regulate target gene expression.

#### *Androgen-AR Interactions and Their Role in CRPC*

Androgen synthesis is initially regulated by the hypothalamic-pituitary-testicular axis [7]. The adrenal glands are then responsible for *de novo* steroidogenesis and the prostate is where these newly synthesized steroids are finally converted to DHT [7]. DHT and T are canonical AR ligands such that when they interact with the AR, they can initiate receptor signaling. Just 15 years ago, it was thought that AR signaling was not involved in castration-resistant prostate cancer (CRPC) biology [7]. However, studies from the past decade have shown that androgens remaining after both physical and chemical castration and the AR itself continue to contribute to CRPC biology and progression [12, 13]. These

studies identified the need for antiandrogen therapies for patients with CRPC. Through a drug discovery screen, the next-generation therapy and AR antagonist, enzalutamide, was identified [14]. Abiraterone acetate is another antiandrogen therapy that was developed for metastatic CRPC patients and specifically inhibits CYP17A1, thereby preventing *de novo* steroidogenesis [15]. Both of these next-generation therapies have been successful in treating CRPC patients; however, overcoming the inherent or acquired resistance to these therapies remains a major clinical challenge.

### *Resistance Mechanisms to Next-Generation Therapies*

Resistance mechanisms to therapies targeting the androgen-AR axis can be broadly categorized into three classes (restored AR signaling, AR bypass signaling, and complete AR independence) based upon clinical relapse profiles and histological and molecular features (Table 3.1) [7]. Restored AR signaling clinically involves AR-positive disease and a rising PSA with histological features of adenocarcinoma. Molecular features characteristic to this class include *AR* genetic alterations such as amplification and mutation, *AR* splice variants, and intratumoral DHT synthesis. Similar to restored AR signaling, AR bypass signaling is characterized by AR-positive adenocarcinomas with a rising PSA; however, the oncogenic addiction to AR signaling is bypassed by upregulation of glucocorticoid receptor signaling [7]. Complete AR independence has histological features of small cell carcinoma (SSC) or neuroendocrine prostate cancer (NEPC) and is characterized clinically by being AR-low or negative with a low

PSA and molecularly by retinoblastoma-associated protein (*RB1*) deletion, tumor protein p53 (*TP53*) deletion/mutation, neuroblastoma MYC oncogene (*MYCN*) gain, and/or aurora kinase A (*AURKA*) gain [7].

Currently, it is difficult to fully discern the role of *AR* mutations in therapy resistance due to several confounding variables. To date, five hotspot LBD mutations have been identified (L702H, W742C, H875Y, F877L, and T878A) in patients [16-20]. Despite having an elevated frequency in CRPC compared to primary prostate cancer (PCa) [16, 17, 21, 22], the overall prevalence of each individual *AR* mutation remains low. Therefore, it is difficult to determine their individual association with therapeutic response. This is further complicated by the fact that *AR* mutations are often detected along with *AR* amplification and/or other *AR* mutations [23]. Additionally, the emergence of both AR bypass signaling and SCC/NEPC in patients with CRPC may hinder our ability to determine the clinical significance of *AR* mutations alone as predictors of therapeutic response to enzalutamide and abiraterone.

Our current understanding of how hotspot *AR* mutations may mediate therapeutic resistance is based upon limited clinical data and pre-clinical studies. Pre-clinical models have shown that AR antagonists can paradoxically function as agonists in the context of certain *AR* LDB mutations [24, 25]. In *in vitro* overexpression studies, the AR antagonist bicalutamide has been shown to have either partial or full agonistic activity to AR L702H, W742C, H875Y and T878A [24] while the next generation therapy enzalutamide has partial agonist activity to AR H875Y, F877L, and T878A [24]. This phenomena has been supported

clinically by some patients who showed clinical improvement following discontinuation of flutamide therapy [7]. Alternatively, some LBD mutations may allow for the promiscuous activation of AR by other steroid ligands such as estrogen, progesterone, and glucocorticoids [7, 24]. A better understanding of this non-specific activity may be of particular importance as the glucocorticoid prednisone is given to patients being treated with abiraterone to prevent mineralocorticoid excess syndrome. In preclinical studies, AR L702H is activated by glucocorticoids and has been found in patients treated with abiraterone. These prior pre-clinical studies examining the role of both hotspot and non-hotspot *AR* mutations have been mostly limited to exogenous *AR* overexpression [24], which less than half the time recapitulates findings in the clinic. Studies have shown that strikingly distinct phenotypes exist between models of exogenous overexpression of gene mutations and gene editing to introduce the mutation [26, 27]. For example, overexpression of *HER2* missense mutations which are rarely seen amplified in patients are far more oncogenic than heterozygous *HER2* missense mutations introduced by gene editing which better recapitulate clinical findings [27]. Overall, these data highlight the need to develop pre-clinical models that reflect patient findings for rigorous investigations of *AR* LBD mutations and therapy resistance.

### *The CRISPR/Cas System*

Clustered regularly interspaced short palindromic repeats (CRISPR) and CRISPR-associated (Cas) genes are the main elements of a microbial adaptive

immune system [28-32]. To date, three types (I-III) of CRISPR/Cas systems have been identified across bacteria and archaea [30]. However, every system ultimately involves the cleavage of foreign nucleic acids by RNA-guided nucleases, which are encoded for in the Cas genes. It was discovered that microbes contain genetic loci with distinctive repetitive elements interspaced with short variable sequences or protospacers [33]. These protospacers were found to be derived from exogenous DNA sources, such as viruses or plasmids, and each protospacer was always associated with a protospacer adjacent motif (PAM) [34-36]. The sequence of the PAM was also discovered to be specific to the type of CRISPR/Cas system being utilized by that given species of bacteria or archaea [35, 36]. Together, the protospacers, PAMs, and interspersed foreign genetic elements constitute the CRISPR RNA (crRNA) array. The crRNA array encodes the guide RNAs or the sequences that the Cas nuclease will use in order to recognize and target foreign nucleic acids for cleavage [35]. The CRISPR/Cas systems also require a trans-activating crRNA (tracrRNA), which facilitates the processing of the crRNA into discrete units [32, 37]. Once the Cas protein associates with the tracrRNA and guide RNA, it can target an invading pathogen for destruction by creating a Watson-Crick base pairing between its specific guide RNA and the pathogen's complementary nucleic acid sequence.

The Type II CRISPR system specifically consists of the Cas9 nuclease and guide RNAs that are 20 nucleotides in length [32, 37-40]. Additionally, the wild-type (WT) Cas9 derived from *Streptococcus pyogenes* targets the complementary foreign DNA of its guide RNA for cleavage when the sequence

immediately precedes a 5'-NGG PAM, thereby making a blunt cut between the 17th and 18th bases in the target sequence (or three base pairs 5' of the PAM) [38]. To date, the Cas9 protein has been optimized for expression in mammalian cells, where it has been shown to maintain its nuclease function [41-44]. Furthermore, Jinek et al. (2012) showed that the required crRNA and trcrRNA for Cas9 function could be fused together, creating one single-guide RNA (sgRNA) [38]. Thus, by altering the 20-nucleotide guide sequence within the sgRNA, Cas9 can target any sequence of interest for cleavage in mammalian cells as long as it falls within the vicinity of the PAM sequence. The HNH and RuvC nuclease domains of Cas9 are responsible for its ability to target sequences for cleavage and, hence, create double strand breaks (DSBs) [39]. Meanwhile, an aspartate-to-alanine mutation in the RuvC catalytic domain (D10A) causes the Cas9 mutant to nick rather than cleave the nucleic acid sequence of interest [37, 38]. Thus, the Cas9 nickase mutant (Cas9n) yields single-strand breaks, and in particular, the SpCas9n only nicks between the 17th and 18th bases in the target sequence.

DSBs in DNA can be particularly harmful for a cell if no attempt to repair them is made [45]. Thus, two main DNA repair mechanisms in order to correct DSBs have evolved in eukaryotic cells [45, 46]. The first mechanism of DSB repair is non-homologous end joining (NHEJ). NHEJ involves the broken ends of DNA being ligated, often resulting in INDEL mutations. The second mechanism of DSB repair is homology-directed repair (HDR). HDR is the precise editing of a damaged locus when a sister chromosome or homologous template is available.

CRISPR/Cas9 gene editing studies have exploited these two types of DSB repair in order to create knockout and knock-in (KI) mutations in genetic loci of interest [41-44, 47]. However, many CRISPR/Cas9 studies have also illustrated that while each base within the 20-nucleotide guide sequence contributes to overall Cas9 specificity, multiple mismatches between the sgRNA and a particular nucleotide sequence can be tolerated, leading to many off-target DSBs and unwanted INDEL mutations [41, 48-50]. Single-strand nicks are usually repaired by the base excision repair (BER) pathway, which potentially results in decreased off-target INDEL mutations [51]. However, while targeting a region of interest with one nickase limits off-target effects of the CRISPR/Cas9 gene editing system, it does not necessarily result in a desired knockout or KI mutation of the targeted locus due to the fact that the cell will preferentially use BER to resolve this lesion.

Ran et al. (2013) developed a double nickase strategy that involves two Cas9n plasmids, each with sgRNAs that are slightly off-set and complementary to opposite strands of the target site [52, 53]. Nicking both DNA strands simultaneously by a pair of Cas9 nickases leads to a site-specific DSB. This DSB can then be repaired by either NHEJ or HDR. Thus, the CRISPR/Cas9 double nickase system increases the specificity of Cas9n's target recognition, while also allowing Cas9n to modify a region of interest at a rate similar to WT Cas9.

### *Translational Relevance of the Isogenic Models with AR LBD Mutations*

Due to the increased Cas9n specificity and similar rates of genome modification with WT Cas9, the CRISPR/Cas9 double nickase system was chosen to generate a novel, isogenic panel of PCa cell lines, all of which contain hotspot *AR* LBD mutations. The four PCa cell lines that were chosen for *AR* gene editing were LNCaP, LAPC-4, VCaP, and CWR22Rv1 (or 22Rv1). These androgen responsive cell lines were chosen for this panel because they are commonly used in research and recapitulate a spectrum of *AR* genomic statuses seen in patients with CRPC. The experimental goal of this study was to first introduce individual missense mutations into the *AR* genetic locus in all of these cell lines using two Cas9n-sgRNA complexes and a repair template (RT) containing a particular *AR* LBD mutation (Figure 3.2A). In other words, after a DSB is created by the double nickases within the *AR* genetic locus, the cell would preferentially repair this damage by HDR (i.e. using the provided RT) and, thereby, KI to its genome the desired *AR* LBD mutation.

Currently, it is unknown if any single and/or combination of *AR* LBD mutations detected in patient cell-free DNA by next-generation sequencing are predictive of either innate or acquired resistance to next-generation therapies. Consequently, how *AR* mutational status should influence therapy selection for men with CRPC has not been determined. By generating novel isogenic cell line models, the biologic role of these *AR* mutations as well as their role in resistance to contemporary androgen-AR axis therapies can be elucidated. Thus, the

findings from these isogenic models have the ability to influence the clinical management of men with metastatic PCa who have somatic *AR* mutations.

## **Materials and Methods**

### *CRISPR/Cas9 Double Nickase Design and Preparation*

The pSpCas9n(BB)-2A-Puro (PX462) V2.0 nickase plasmid was originally purchased by Dr. Ben H. Park (Johns Hopkins School of Medicine (JHSoM), Baltimore, MD) from Addgene. PX462 was then molecularly cloned, purified, and digested with BbsI (New England Biolabs, Inc.) by Dr. W. Brian Dalton. Since a CRISPR/Cas9 double nickase strategy was determined to be ideal for *AR* genomic targeting, the digested PX462 was used to create two, guide-specific Cas9 plasmids (or Cas9 protein guides). In order to transform PX462 into two Cas9 protein guides, the online CRISPR Design Tool (<http://tools.genome-engineering.org>) was used to determine the optimal, offset 20-nucleotide guide sequences within the given *AR* genomic target sequence of interest. These two Cas9 Guides were designed 18 nucleotides apart in *AR*, intron 7 and were confirmed to not be in a region involved in splicing by the online Human Splicing Finder ([www.umd.be/HSF/](http://www.umd.be/HSF/)). The CRISPR Design Tool identified two PAMs (CCC and GGG) and the 20-base sequences (5'-aggaagtacggggaagggg-3' and 5'-agacaaaaatcagaggtg-3') downstream and upstream of the PAMs for the generation of Cas9 Guide 1A and 1B, respectively. From these two, 20-base

sequences, the sgRNAs sequences were designed and purchased as oligos from IDT as follows: Guide 1A forward: 5'-caccgcccccttccccgtacttct-3'; Guide 1A reverse: 5'-aaacaggaagtacggggaagggggc-3'; Guide 1B forward: 5'-caccgagacaaaaatcagaggttg-3' Guide 1B reverse: 5'-aaaccaacctctgatttttggtctc-3'. Each forward and reverse oligo for a given Cas9 Guide was annealed in a PNK buffer reaction provided by Dr. W. Brian Dalton and using the following cycling conditions: (1) 95°C for 5 minutes; (2) ramp down to 25°C at 5°C per minute; (3) dilute annealed oligos 1:200 with UltraPure™ Distilled Water (Invitrogen). Each diluted, annealed oligo pairing of sgRNAs was ligated to PX462 separately, using New England Biolab, Inc.(NEB)'s Quick Ligase as per the manufacturer's protocol. The ligation reactions were cleaned up by a QIAquick PCR Purification Kit (Qiagen), transformed into Invitrogen's One Shot® TOP10 Electrocomp™ E. coli, and plated on LB-Ampicillin (50µg/mL) plates overnight. Colonies were PCR-screened by Phusion® Hot Start Flex DNA Polymerase (NEB) as per the manufacturer's protocol and using the following primers: forward primer 216 (5'-cctctgacttgagcgtcgat-3') and reverse primer 871 (5'-ggggcgctacttggcatatgata-3'). The annealing temperature for these primers was 66.3°C with an extension time of 30 seconds. All positive colonies were prepared using Qiagen's Plasmid Maxi Kit, thereby creating Cas9n Guide 1A and 1B. Glycerol stocks of each positive colony were also prepared and stored at -80°C.

### *CRISPR/Cas9 RT Design and Preparation*

The first two, hotspot mutations in *AR*, exon 8 to be chosen for targeting by the CRISPR/Cas9 double nickase system were F877L and T878A. Three, 323-base pair RTs were generated for this region, each spanning the *AR*, intron 7/exon 8 boundary of interest (gBlocks Gene Fragments, IDT). The gBlock RTs were homologous to the region except for the single nucleotide missense mutation of interest, the inclusion of the M13F primer sequence (5'-tgtaaacgacggccagt-3') to be inserted into the intron in order to mutate Guide 1A's PAM and for target-specific PCR amplification, and the sequence (TTA) to mutate the PAM sequence of Guide 1B to prevent re-targeting after incorporation. The gBlock RT names and sequences are as follows (with mutated bases in **bold**): (1) RT1-WT: 5'-

a-3'. All gBlock RTs were PCR-amplified by Phusion® Hot Start Flex DNA

Polymerase (NEB) as per the manufacturer's protocol and then validated by  
Sanger sequencing (JHSoM Genetic Recourses Core Facility). The forward  
primer (gBlock-F1) for PCR amplification was 5'-

tctttctctctctcgtgtctctcttaacacacacacacacacacacgacctcatgg-3' and the reverse  
primer (gBlock-R1) was 5'-ccaatgcttactgggtgtgg-3'. These primers had an  
annealing temperature of 67°C with an extension time of 30 seconds and  
extended each gBlock RT to a size of 359 nucleotides. PCR reactions were  
cleaned up using a QIAquick PCR Purification Kit (Qiagen) as per the  
manufacturer's protocol, and both gBlock-F1 and gBlock-R1 were used as  
sequencing primers in the Sanger sequencing reactions.

### *Cell Lines and Culture*

22Rv1, LAPC-4, and VCaP cells were gifts of Dr. John Isaacs (The Johns Hopkins University, Baltimore, MD). LNCaP cells were obtained from the American Type Culture Collection (ATCC; Manassas, VA). LNCaP and 22Rv1 cells were cultured in growth medium (RPMI-1640 (Gibco) supplemented with 10% (vol/vol) FBS (Corning) and 1% (vol/vol) Pen Strep (P/S; Gibco)). LAPC-4 cells were cultured in growth medium (IMDM (Gibco) supplemented with 10% (vol/vol) FBS and 1% (vol/vol) P/S). VCaP cells were cultured in growth medium (DMEM, High Glucose (ATCC) with 10% (vol/vol) FBS and 1% (vol/vol) P/S).

### *Cell Line Transfections with CRISPR/Cas9 Reagents*

All cell lines were plated in 6-wells at a concentration of  $6 \times 10^5$  cells per well in their respective growth medium. When cells reached 80% confluency (24 to 48 hours after being plated), each well was washed with 1X PBS (Gibco). Cells were then incubated for two hours in antibiotic-free growth medium with 10% (vol/vol) FBS only. Transfection reactions were set up according to Promega's FuGENE HD Transfection Reagent Technical Manual. Each 150uL transfection reaction for a given 6-well contained a total of 2.85ug total DNA (1250ng RT, 800ng Guide 1A, and 800ng Guide 1B), 11.4uL FuGENE HD (which is a 4:1 ratio of ug total DNA to uL FuGENE HD), and remaining amount of Opti-MEM I (Gibco). Each transfection reaction incubated for 5 minutes at room temperature. After the two-hour incubation, the antibiotic-free growth media with 10% (vol/vol) FBS only was refreshed on each 6-well of cells, and the given

150uL transfection reaction was added to the well. After 48 hours, half the transfected cells of a 6-well were taken for genomic DNA (gDNA) isolation, meanwhile the remaining half of the transfected cells were maintained in cell culture for single cell isolations.

### *gDNA Isolations and Single Cell Isolations*

All gDNA isolations of transfected cell pools were performed with Qiagen's DNeasy Blood and Tissue Kit as per the manufacturer's protocol. As for single cell isolations, each pool of transfected cells was counted, and serial dilutions were performed in respective media in order to plate 48, 96, 192, or 288 cells per 96-well plate (or 0.5, 1, 2, or 3 cells per 96-well). Plates were checked and marked weekly for wells that contained the growth of single cell colonies. Once wells containing a single cell colony had reached greater than 50% confluency (2-4 weeks depending on the given cell line), the cells of a given well were trypsinized (0.25% Trypsin, 2.21mM EDTA; Corning) and replica plated between two 96-well plates. Once the cells in the duplicated 96-well plates reached greater than 80% confluency, gDNA was isolated from an entire 96-well plate, using Promega's Wizard SV 96 Genomic DNA Purification System as per the manufacturer's protocol. The gDNA was then PCR-screened for positive clones that had successfully undergone HDR with the CRISPR RTs. All positive clones were taken from the duplicated and remaining 96-well plate and expanded, maintained, and frozen down for experimental purposes.

### *PCR Screens for CRISPR-positive Clones*

Due to difficulty amplifying the region of interest from these 96-well plates, all gDNA isolated from these transfected cell lines underwent nested PCR amplification in order to initially screen for the single cell isolated clones that successfully underwent HDR, utilizing the provided gBlock RTs. First, a region of 874 bases was PCR-amplified from the gDNA using Invitrogen's Platinum™ *Taq* DNA Polymerase as per the manufacturer's protocol. This region completely surrounds the PAM sites in *AR*, intron 7, the single base substitution site in *AR*, exon 8, and the gBlock RTs. The forward primer (F1) sequence for this PCR is as follows: 5'-GTGGTGAAGAAAAGAACACGG-3'. The reverse primer (R1) sequence for this PCR is as follows: 5'-GCCCAGCAAATAGAATTCAGG-3'. The annealing temperature for this primer pair was 58.8°C with an extension time of one minute. Then, the PCR product from this first PCR was used as the product for the second, nested PCR and amplified using Invitrogen's Platinum™ *Taq* DNA Polymerase as per the manufacturer's protocol. The product size for the nested PCR is 442 bases, which still encompasses the majority of the gBlock RT design. The forward primer (M13F) sequence for the nested PCR is as follows: 5'-TGTA AACGACGGCCAGT-3', which contains the mutated PAM 1 sequence in the gBlock RTs. The reverse primer sequence for this nested PCR is the same as R1. The annealing temperature for this primer pair was 56.5°C with an extension time of 30 seconds. Single cell colonies containing the positive, 442-base band were trypsinized from the duplicated 96-well plates and expanded for experimental purposes. Please note that isolated gDNA from the transfected cell

pools only underwent the one, nested PCR with primers M13F and R1 for screening purposes. The nested PCR product from both the 96-well plates and the transfected cell pools was gel isolated using Qiagen's QIAquick Gel Extraction Kit as per manufacturer's protocol and sent for Sanger sequencing. The M13F or the R1 primer was used as the sequencing primer in these reactions. As the single cell clones were expanded and maintained, gDNA was continuously isolated, nested PCR-screened, and Sanger sequenced to confirm CRISPR/Cas9-edited genomic status.

#### *Droplet Digital PCR (ddPCR)*

ddPCR for determining the *AR* copy number of parental cell lines and CRISPR/Cas9-edited cell clones was performed largely as described previously [23, 54]. In order to confirm the *AR* genomic status as either WT or mutant of all parental and CRISPR/Cas9-edited cell lines, isolated gDNA was digested with *MseI* (NEB) and cleaned using a QIAquick PCR Purification Kit (Qiagen) as per the manufacturer's protocol. WT and mutant probes to *AR*, exon 8 were designed and ordered from IDT as follows: WT probe (HEX):

ATCAGTTCACCTTTTGACCTGCTA; F877L probe (FAM):

ATCAGCTCACTTTTGACCTGCTA; and T878A probe (FAM):

ATCAGTTCGCTTTTGACCTGCTA. WT control genomic female and male DNA (Promega) digested with *MseI* as well as the gBlock RTs for the particular mutation were used as ddPCR controls. ddPCR (Bio-Rad) was performed in a dedicated, ultraviolet (UV)-equipped hood and according to the manufacturer's

protocol. Total molecules were quantified and analyzed by the QX200 Droplet Reader software.

## **Results**

### *Initial Nested PCR Screens of All Transfected Cell Lines*

Initial nested PCR screens of LNCaP, LAPC-4, 22Rv1, and VCaP gDNA successfully amplified the expected, 442-base pair (bp) band from the CRISPR/Cas9n reagent-transfected cell line pools and did not amplify any DNA fragment from the non-transfected cell line pools (i.e. negative controls; Figure 3.2B). Sanger sequencing of the gel isolated, nested PCR product showed both the parental *AR*, intron 7 and exon 8 sequences as well as the expected KI point mutations provided by the RTs. Both parental and KI RT mutations are present in the transfected cell line gDNA because the transfection rate of any population of cells is not 100%, and therefore, these cell pools still contain both transfected and non-transfected cells. In addition, the CRISPR/Cas9n reagent-transfected cells within these pools may not have completely utilized the RT to repair the *AR* genomic locus after the DNA had been nicked; hence, this gDNA may also contain cells with complete and incomplete RT KIs.

### *LNCaP-CRISPRed Cell Lines*

Sixteen, 96-well plates for single cell dilutions were used for each of the transfected LNCaP cell pools. Since there was a separate transfection for each RT (WT, F877L, and T878A), a total of 48 plates were created and then visually screened by an inverted microscope over a period of four weeks for wells containing single cell colonies. From these 48 plates, only a total of 480 wells contained single cell colonies and were, therefore, replicated between two 96-well plates. Thus, it is estimated that 160 single cell colonies were replica plated for each RT transfection. All of these 480 single cell colonies (growing in a total of 5, 96-well plates) were screened by two PCRs (including the nested PCR) for cells that had successfully undergone HDR with the provided RT. From the LNCaP cells transfected with the WT RT (LNCaP-WT), only 1 single cell colony was found by this PCR screen. For the LNCaP cells transfected with the F877L and T878A RTs (LNCaP-F877L and LNCaP-T878A, respectively), two LNCaP-F877L and three LNCaP-T878A clones were identified. Thus, a total of 6 clones (out of a total of 480 or 1.3% of clones) were found to have utilized the provided RT to repair the double-stranded nicks created by Guides 1A and 1B within *AR*, intron 7. Each CRISPR-positive, 442-bp band amplified from these six single cell colonies in the second PCR (or nested PCR) was gel isolated and sent for Sanger sequencing. The gDNA from these same six cell lines was also digested in order to determine the genomic status of the entire cell colony by ddPCR. In the meantime, it took two months to expand these six cell colonies from the second replica plate. When cell lines were at a point of freezing down, gDNA was

again isolated in order to perform a nested PCR screen as well as additional Sanger sequencing and ddPCR assessments.

It was determined by Sanger sequencing and ddPCR that not one of these six, CRISPR-positive LNCaP colonies was a homogeneous cell population (i.e. a cell line that was expanded from a single cell). Therefore, an aliquot of each line was taken before completing freezing them down and single cell dilutions into 96-well plates were performed for a second time. Four, 96-well plates (each diluted at 1 cell per well) were created for each CRISPR-positive cell line. From a total of 24 plates, only a combined total of two 96-well plates were created for replication. Thus, only 12-32 single cell colonies were isolated per original CRISPR-positive cell line. Interestingly, when both of these 96-well plates were PCR-screened, the single cell colonies from four of these six original CRISPR-positive cell lines screened completely negative (i.e. did not amplify the 442-bp band). In fact, only single cell colonies from two of these original CRISPR-positive cell lines amplified the 442-bp band. Thus, the second single cell dilutions of the original six CRISPR-positive LNCaP cell lines yielded only a total of six CRISPR-positive colonies from the LNCaP-WT line and one CRISPR-positive colony from a LNCaP-T878A line. These seven, CRISPR-positive colonies from the second attempt at single cell dilutions were expanded and frozen down.

The 442-bp bands amplified from the six, second dilution LNCaP-WT cell lines during the nested PCR screen were gel isolated and Sanger sequenced. From these results, it was concluded that these cell lines were still not

homogeneous populations and that isolating single LNCaP cells in 96-well plates may be more difficult than originally anticipated. Therefore, an original stock of the LNCaP-WT clone was defrosted for a third single cell isolation. For this third attempt at single cell isolations, the LNCaP-WT cells were diluted across 16, 96-well plates (i.e. four plates per cell dilution) containing a feeder layer of irradiated NIH 3T3 cells. From these 16 plates, a total of four, 96-well plates of single cell clones were created for replication. Interestingly, when these four plates were screened by nested PCR, the majority (>90%) of the wells were CRISPR-positive (i.e. most of the colonies contained cells that had utilized the RT during HDR). Twenty-one single cell colonies were chosen randomly from these four plates and taken for expansion. The 442-bp bands from the nested PCR screen of these 21 colonies were gel isolated and Sanger sequenced. The gDNA from nine of these 21 colonies was also digested for ddPCR. Since all of these LNCaP-WT colonies had very similar Sanger sequencing and ddPCR results (Figure 3.3A), it was concluded that there was most likely not an issue with how the cells were single cell isolated for the third time. In fact, ddPCR results of the parental LNCaP cell lines (i.e. before transfection with the CRISPR/Cas9n reagents) confirm that these cells have two copies of the *AR* gene (Table 3.2). Thus, the single cell colonies isolated from LNCaP-WT for the third time are most likely homogeneous populations of cells where only one of the *AR* alleles has been targeted by the nickases and repaired using the WT RT. Additionally, RNA was isolated and cDNA was synthesized from two of these LNCaP-WT single cell colonies. The cDNA from these two colonies was assessed by ddPCR in order to

determine which allele (WT or T878A) is being expressed. While the majority of the cDNA being expressed by these colonies contained the parental sequence (T878A), these colonies were also expressing the knocked-in WT allele at very low levels (Figure 3.4A).

#### *LAPC-4-CRISPRed Cell Lines*

The first set of LAPC-4 single cell dilution plates (total=16, 96-well plates per RT) were set up similarly to the first set of LNCaP single cell dilution plates. However, for the LAPC-4 single cell isolations, only a total of 430 single cell colonies (or ~140 colonies per RT transfection) were replica plates into an initial 4.5, 96-well plates. Interestingly, a total of 6 clones (out of a total of 430 or 1.4% of clones) were found by PCR screening to have utilized the provided RT to repair the double-stranded nicks created by Guides 1A and 1B within *AR*, intron 7. From the LAPC-4 cells transfected with the WT RT (LAPC-4-WT), only 1 single cell colony was found by this PCR screen. For the LAPC-4 cells transfected with the F877L and T878A RTs (LAPC-4-F877L and LAPC-4-T878A, respectively), two LAPC-4-F877L and three LAPC-4-T878A clones were identified. Each CRISPR-positive, 442-bp band amplified from these six single cell colonies in the nested PCR was gel isolated and sent for Sanger sequencing, while the gDNA from these same six cell lines was also digested in order to determine the genomic status of the entire cell colony by ddPCR (Figure 3.3B). In the meantime, it took 3.5 months to expand these six LAPC-4 cell colonies from the second replica plate. When cell lines were at a point of freezing down, gDNA

was again isolated in order to perform a nested PCR screen as well as additional Sanger sequencing and ddPCR assessments.

Since it was determined by Sanger sequencing and ddPCR that not one of these six, CRISPR-positive LAPC-4 colonies was a homogeneous cell population, an aliquot of each line was taken before completely freezing them down and single cell dilutions into 96-well plates for a second time were performed. Similar to the second single cell dilutions of LNCaP cells, only a combined total of two 96-well plates were created for replication. Thus, only 12-32 single cell colonies were isolated per original CRISPR-positive cell line. Interestingly, when both of these 96-well plates were PCR-screened, the single cell colonies from three of these six original CRISPR-positive cell lines screened completely negative. In fact, only single cell colonies from three of these original CRISPR-positive cell lines amplified the 442-bp band. Thus, the second single cell dilutions of the original six CRISPR-positive LAPC-4 cell lines yielded only a total of one CRISPR-positive colonies from LAPC-4-WT, 12 CRISPR-positive colonies from a LAPC-4-F877L line, and nine CRISPR-positive colonies from a LAPC-4-T878A line. However, only seven and nine colonies of these second dilution LAPC-4-F877L and T878A lines, respectively, were able to be expanded and frozen down. The 442-bp bands amplified by the nested PCR screen from these 16, second dilution LAPC-4-F877L and T878A cell lines were gel isolated and Sanger sequenced. From these results, it was concluded that all seven of the LAPC-4-F877L cell lines contained gDNA with the F877L missense mutation as well as the parental cell line's sequence, making it a heterogeneous or mixed

population of cells. However, all nine of the LAPC-4-T878A cell lines looked like homogeneous cell populations as they only contained the T878A missense mutation in their Sanger sequencing results. However, these results still need to be confirmed by ddPCR.

ddPCR results of the parental LAPC-4 cell lines (i.e. before transfection with the CRISPR/Cas9n reagents) confirm that these cells have one copy of the *AR* gene (Table 3.2). Thus, the single cell colonies isolated from the first single cell dilutions of the transfected LAPC-4 cells as well as the LAPC-4-F877L cell lines from the second attempt at dilutions are most likely heterogeneous or mixed populations of cells. Additionally, RNA was isolated and cDNA was synthesized from two of these single cell colonies isolated from LAPC-4-F877L for the second time. The cDNA from these two colonies was then assessed by ddPCR in order to determine if there were cells in these populations expressing *AR* WT or F877L. The cDNA being expressed by both of these colonies contained the parental sequence (WT) and the mutated sequence (F877L) at very similar levels (Figure 3.4B).

#### *22Rv1-CRISPRed Cell Lines*

A total of 24, 96-well plates (or eight plates per RT) were originally set up for single cell dilutions of all 22Rv1 cell lines transfected with CRISPR/Cas9n reagents. Within five weeks, 200 single cell colonies per RT were replica plated. From initial PCR screens, two WT, five F877L, and five T878A colonies were CRISPR-positive. These 12 colonies (or 2% of the total colonies) were

expanded over four weeks. Of these 12 CRISPR-transfected cell lines, only 1 targeted WT, four F877L, and two T878A cell lines were able to be grown and expanded. Through Sanger sequencing, it was discovered that two of the 22Rv1-F877L lines did not contain the intended F877L mutation, thereby creating CRISPR-targeted controls for the 22Rv1 cell lines. Sanger sequencing results for the five other CRISPR-positive cell lines show that both the particular knocked-in missense mutation and parental line sequences are present. Thus, these five CRISPR-positive 22Rv1 cell lines remain as mixed cell populations with targeted and non-targeted cells or as homogeneous cell populations with at least one *AR* allele targeted. Since the *AR* copy number status for parental 22Rv1 cells is still being assessed (Table 3.2), no conclusions about these lines have been made as of yet.

#### *VCaP-CRISPRed Cell Lines*

A total of 36, 96-well plates (or 12 plates per RT) were originally set up for single cell dilutions of all VCaP cell lines transfected with CRISPR/Cas9n reagents. It took two months to collect ~75 single cell colonies per RT for replication, and it was an additional five months after replication before these single cell colonies grew to about 80% confluency and could be screened. Through PCR screening, three WT, five F877L and 10 T878A CRISPR-positive colonies were initially discovered. However, it took an additional six months to expand these single cell colonies from the 96-well replica plates and not every colony survived. From these 18 original CRISPR-positive VCaP colonies, only

three WT, two F877L, and seven T878A colonies survived the process of expansion. From these 12 single cell colonies, gDNA was isolated before freezing stocks of each CRISPR-positive cell line. However, it was decided to delay additional screens on these CRISPR-positive cell lines since these particular cell lines took over a year to grow. Interestingly, when a second transfection of VCaP cells with the CRISPR/Cas9n reagents was performed, an additional eight, 96-well plates per RT (i.e. a total of 24 plates) were created; however, no single cell colonies were visible after three months. Thus, no replica plates could be made or screened. In addition to growing poorly after transfection, parental VCaP cell lines were found to contain increased *AR* copy number by ddPCR (Table 3.2). It is still being considered whether or not this copy number gain could be interfering with the targeting of the *AR* genetic locus by the CRISPR/Cas9n system.

## **Discussion and Future Directions**

CRISPR/Cas9 is a relatively new gene editing method and consequently protocols for using this system are still being optimized. While this study demonstrates that the CRISPR/Cas9n system can be used to introduce *AR* genetic mutations in several PCa cell lines (including LNCaP, LAPC-4, 22Rv1, and VCaP), there are a few limitations of this study that need to be addressed since none of the generated cell lines can be utilized in experiments as of yet.

The first limitation of this study is the type of CRISPR/Cas9n system that was utilized. While the double nickase system does limit off-target mutagenesis, a recent study has suggested that the efficiency of the system could be further increased if the Cas9n plasmids directly target the region of interest's exon for nicking and if the provided RTs are much shorter [55]. Another study has suggested combining CRISPR/Cas9 gene editing technology with recombinant adeno-associated virus (rAAV) genome editing technology such that the designed RT contains a selection cassette in addition to the mutations of interest [56]. This technique would then allow for the selection of cells that specifically utilized the RT to repair the double-strand break introduced by the nickases and would, thereby, also increase the rate of finding CRISPR-positive single cell clones after the initial transfections.

Another limitation of this study was the initial single cell isolation protocol that was used. This protocol originally involved the significant dilution of the cell population across 96-well plates; however, it became evident that after transfection, these PCa cell lines were very sensitive and seemed to only grow in a non-single cell state. The best single cell isolation results in this study were seen with the LNCaP-WT line, which was single cell isolated for a third time in plates containing a feeder layer of irradiated NIH 3T3 cells. In addition to using feeder layer cells, cloning cylinder technology could also be employed to isolate single, CRISPR-positive cells. This technique involves cells being distributed across a large enough surface area so that individual cells can grow without interacting with other growing colonies and in continuously conditioned media.

This method is particularly useful when single cells cannot grow without paracrine signaling. Thus, all of the remaining CRISPR-positive LNCaP, LAPC-4, and 22Rv1 cell lines will need to be properly single cell isolated using a different protocol.

In addition to re-isolating single cell clones from each of the CRISPR-positive lines and redesigning the CRISPR/Cas9 gene editing system, the LNCaP-WT cell line that has already been properly single cell isolated (and all other CRISPR-positive LNCaP cell lines that will undergo single cell dilution) will need to endure further gene editing in order to introduce the *AR* LBD sequences of interest into the second *AR* allele. Once the entire panel of isogenic PCa cell lines with *AR* LBD mutations has been generated, a unique and valuable resource will be available for many future studies. Future studies will comprehensively examine these cell lines for genetic and epigenetic alterations as well as differences in overall gene expression. These cell lines will also be valuable pre-clinical substrates for drug design and testing. Ultimately, by generating novel isogenic cell line models, the biologic role of these *AR* mutations as well as their role in resistance to contemporary androgen-AR axis therapies can be elucidated. Consequently, how *AR* mutational status should influence therapy selection for men with CRPC can be determined.

**Figure 3.1.** Schematic of the domain structure of AR, highlighting the location of cancer-associated LBD hotspot mutations.

**Figure 3.2.** Schematic of CRISPR/Cas9n gene targeting scheme for *AR* in PCa cell lines. A) CRISPR-targeting strategy for *AR* WT, T878A, and F877L. Intronic barcodes for amplification were introduced into the *AR* genetic locus for targeted parental identification (mPAM1-M13F and mPAM2-TTA). B) Representative image of PCR-amplified gDNA using the M13-Forward internal barcode specific primer and the 3'-UTR-Reverse primer outside of the targeting region. The gDNA in this particular PCR was from VCaP cells either not transfected with

CRISPR/Cas9n reagents (i.e. negative control; Lane 1) or transfected with CRISPR/Cas9n reagents (WT, F877L, and T878A RTs; Lanes 2-5, respectively). Lane 5 represents a water (or negative) control.

**Figure 3.3.** Representative Sanger sequencing and ddPCR results for PCa cell lines, all of which were single cell isolated after transfection with CRISPR/Cas9n reagents. A) Results for a LNCaP cell line transfected with the WT RT. B) Results for a LAPC-4 cell line transfected with the T878A RT.

**Figure 3.4.** Determining the *AR* gene expression status of CRISPR/Cas9n-transfected PCa cell lines by assessing cDNA via ddPCR. ddPCR results for (A) two LNCaP-WT cell lines that were single cell isolated during the third attempt and for (B) two LAPC-4-F877L cell lines that were originally thought to be single cell isolated during the second attempt, but most likely remained a mixed population of targeted and non-targeted cells. Positive controls for both ddPCRs include: AR T878A and F877L gBlocks (mutant probe controls), Female gDNA digested by MseI (WT probe control), and a given cDNA control for each of the parental cell lines. A water (or negative) control was also utilized.

(443) 287 – 0877 || storqua1@jhmi.edu

### EDUCATION

- Johns Hopkins School of Medicine**, Baltimore, MD 2014 – 2018  
Ph.D. in Cellular and Molecular Medicine  
Preparing Future Faculty Teaching Academy Certificate
- Smith College**, Northampton, MA 2007 – 2011  
B.A. in Biological Sciences and Mathematics  
High Honors in Biological Sciences  
Associate Member of Sigma Xi, The Scientific Research Society  
First Group Scholar 2009 – 2011 (top 10% of the Class of 2011)  
Dean's List 2008 – 2011  
Massachusetts Initial Teacher License in Mathematics – Grades 8-12

### RESEARCH EXPERIENCE

- Johns Hopkins School of Medicine**, Baltimore, MD 2015 – 2018  
Ph.D. Candidate in the Laboratory of Paula J. Hurley, Ph.D.  
Dissertation Title: *Genetic Alterations in Prostate Cancer: Evaluating Their Biomarker Potential and Roles in Therapeutic Response and Resistance*
- Brigham and Women's Hospital, Department of Medicine – Cardiovascular Medicine**, Boston, MA 2012 – 2014  
Technical Research Assistant II in the Laboratory of Jane A. Leopold, M.D.
- Brigham and Women's Hospital, Department of Medicine – Gastroenterology**, Boston, MA 2011 – 2012  
Technical Research Assistant II in the Laboratory of Richard Blumberg, M.D.
- AB Biosciences, Inc.**, Allston, MA, **Research Assistant** 2011
- Smith College**, Northampton, MA 2008 – 2011  
Honors Thesis Student in the Laboratory of Robert Merritt, Ph.D.  
Honors Thesis in Biological Sciences: *An Exploration of Restricted Lactate Dehydrogenase Subunit Association*
- University of Massachusetts**, Amherst, MA, **Laboratory Assistant** 2010

## **Smith College participates in the Summer Black-Footed Ferret Survey,**

Logan County, KS

2009

Student Research Assistant in the Laboratory of Steven Williams, Ph.D.
